SELF-ASSESSMENT QUESTIONS

1. Which of the following drug properties limits the ability of a drug to readily transfer across the placenta?

   A. Low protein binding

   B. Molecular weight above 1,000 Da

   C. Lipophilicity

   D. Weak base

2. A 34-year-old patient is attempting pregnancy. Their past medical history is complicated by obesity (current BMI 32 kg/m^2), gastroesophageal reflux disease, type 2 diabetes, and hypothyroidism. They are currently on omeprazole 20 mg and levothyroxine 100 mcg daily. What is the best recommendation for starting folic acid supplementation?

   A. Start folic acid 0.4 mg daily once pregnancy is confirmed

B. Start folic acid 0.4 mg daily before trying to conceive, and continue through at least the first trimester of pregnancy

C. Start folic acid 4 mg daily once pregnancy is confirmed

D. Start folic acid 4 mg daily before trying to conceive, and continue through at least the first trimester of pregnancy

3. The patient in Question 2 also asks what they should do with their diabetes medications. They are currently taking liraglutide and canagliflozin. They tell you that they couldn't tolerate metformin. Their A1c is 7.8% (0.078; 62 mmol/mol). What is the best recommendation?

A. Continue liraglutide and canagliflozin

B. Stop both medications and start insulin

C. Continue liraglutide and canagliflozin and add glyburide

D. Stop both medications and start metformin

4. A 29-year-old pregnant individual is at 30 weeks gestation, and reports new onset straining and difficulty to pass bowel movements, despite increasing their dietary fiber and water intake. They report currently having a bowel movement every other day. Prior to pregnancy, the patient reports they had regular bowel movements daily. Which of the following recommendations is the most appropriate?

A. Psyllium

B. Docusate

C. Bisacodyl

D. Senna

5. A 36-year-old individual is currently at 9 weeks gestation and has a history of preeclampsia during their last pregnancy 3 years ago. Which of the following interventions should be recommended for this patient?

A. Low-dose aspirin today

B. Low-dose aspirin at 12 weeks gestation

C. Aspirin 325 mg daily

D. Aspirin 325 mg daily at 12 weeks gestation

6. An individual at 34 weeks gestation develops a deep vein thrombosis. What is the best treatment to initiate?

A. Warfarin

B. Rivaroxaban

C. Enoxaparin

D. Fondaparinus

7. A 28-year-old individual at 30 weeks gestation presents to the community pharmacy requesting medication to help with symptoms of GERD. Symptoms are occurring daily, mostly in the evening after dinner. Which of the following is the best choice for treatment?

A. Calcium carbonate

B. Famotidine

C. Omeprazole

D. Nonpharmacological therapy

8. A 32-year-old individual presents to their physician expressing a desire to conceive. They have a history of complex partial seizures since childhood for which they take divalproex sodium ER 1,000 mg twice daily and their last seizure was 6 months ago. Which of the following management strategies would you recommend to reduce the risk of congenital malformations should pregnancy occur?

   A. Switch drug therapy to phenobarbital

   B. Use low doses of several antiseizure medication to minimize dose of each received

   C. Continue divalproex sodium

   D. Medication change to levetiracetam before conception is attempted

9. A 29-year-old individual at 32 weeks gestation presents with an acute migraine headache not responsive to acetaminophen. They report their last migraine was 6 months ago, before conception. Which of the following is an appropriate treatment option?

   A. Sumatriptan

   B. Magnesium supplement

   C. Ibuprofen

   D. Propranolol

10. A 23-year-old individual had intermittent asthma treated with albuterol before pregnancy. Now at 13 weeks gestation they are increasingly having symptoms and meets the definition for mild persistent asthma. The *most* appropriate treatment for this patient is:

   A. Use only albuterol for the duration of the pregnancy

   B. Continue albuterol and add low dose fluticasone/salmeterol

   C. Continue albuterol and add oral prednisone

   D. Continue albuterol and add low dose budesonide

11. At 33 weeks gestation, an individual presents to the local, rural hospital, and is found to be in preterm labor. The team has decided to transfer them to a large medical center that has a neonatal intensive care unit. What is the best recommendation(s) now?

   A. Nifedipine

   B. Nifedipine and betamethasone

   C. Indomethacin

   D. Indomethacin and betamethasone

12. A 23-year-old patient is at their first prenatal visit. They are currently 8 weeks gestation. Laboratory result revealed (+) RPR and syphilis titer of 1:20 and they are diagnosed with late latent syphilis. The patient has an allergy to penicillin with a reaction of hives. What is the best recommendation?

   A. Desensitize with penicillin, and then give penicillin G 2.4 million units intramuscularly for 1 dose

   B. Desensitize with pencillin, and then give penicillin G 2.4 million units intramuscularly weekly for 3 doses

   C. Desensitize with penicillin, and then give ceftriaxone 500 mg intramuscularly for 1 dose

   D. Metronidazole 500 mg by mouth twice a day for 7 days

13. A patient diagnosed with gestational diabetes has failed first-line treatment with dietary and lifestyle modifications. Which of the following is *most* appropriate to use in an individual who refuses insulin?

    A. Sitagliptin

    B. Pioglitazone

    C. Glyburide

    D. Metformin

14. A 28 weeks gestation patient is diagnosed with gestational hypertension today. Their medical history is significant for allergic rhinitis, eczema, and asthma. What is the best recommendation?

    A. Labetalol

    B. Nifedipine

    C. Amlodipine

    D. Hydrochlorothiazine

15. Strategies to lower infant exposure to medications through breast milk include all of the following *except*:

    A. Recommend a drug with a shorter half-life

    B. Recommend a drug with low bioavailability

    C. Recommend a highly protein-bound drug

    D. Recommend a drug with high lipid solubility

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Drugs with a high molecular weight do not substantially cross the placenta. Drugs with low protein binding, lipophilicity, and those that are weak bases all contribute to passage of drug to the placenta. See “Transplacental Medication Transfer” section for additional information.

2. **B.** The American College of Obstetricians and Gynecologists (ACOG) recommends that at least 0.4 mg of folic acid should start 1 month prior to conception and continue throughout at least the first trimester to reduce the risks of neural tube defects. See “Preconception Planning” section for additional information.

3. **B.** According to ACOG, the preferred therapy for diabetes management in pregnancy is insulin. Additionally, the patient has uncontrolled A1c, so achieving control prior to the pregnancy and help further reduce the risks in pregnancy. Neither liraglutide nor canagliflozin are recommended therapies in pregnancy and have limited to no data in pregnancy. See “Glucose Management” section for additional information.

4. **B.** Both docusate and psyllium are recommended agents for constipation in pregnancy. Since the patient is also experiencing straining and has adequate dietary fiber intake, adding the stool softener can help improve symptoms. See “Constipation” section for additional information.

5. **B.** ACOG recommends starting low dose aspirin between 12 and 28 weeks (ideally 12-16 weeks) in patients who have 1 high-risk factor or 2 moderate-risk factors for preeclampsia. This patient has a high-risk factor of history of preeclampsia. See “Complications of Hypertension” section for additional information.

6. **C.** According to ACOG, low-molecular-weight heparin like enoxaparin is the recommended therapy for treatment of acute thromboembolism during pregnancy. Fondaparinux should be avoided unless the patient has a severe heparin allergy. Warfarin is avoided because of its risk of teratogenicity. Due to the limited data with direct oral anticoagulants, these agents are not recommended for use in pregnancy. See “Thromboembolic Disorders”

section for additional information.

7. **B.** An H2 receptor antagonist, like famotidine, is the preferred therapies to prevent against heartburn/GERD symptoms during pregnancy. See “Gastroesophageal Reflux Disease” section for additional information.

8. **D.** Medication change to avoid the use of valproic acid and phenobarbital is suggested before conception is attempted because of known teratogenic risks and the availability of less teratogenic medications. Antiseizure medication monotherapy is recommended with regimen optimization occurring before conception. See “Epilepsy” section for additional information.

9. **A.** Sumatriptan is the least likely to cross the placenta. Ibuprofen should not be used during pregnancy, especially after 20 weeks gestation. Magnesium and propranolol are both used for prophylaxis of migraines. See “Headache” section for additional information

10. **D.** According to recommended step therapy, step 2 adds a low-dose inhaled corticosteroid as the preferred step therapy. Continuing only albuterol for the duration of the pregnancy is inappropriate as the patient’s asthma is uncontrolled. Adding a low dose steroid plus salmeterol would be indicated for step 3 of asthma treatment. Adding an oral steroid would not be recommended as controller therapy as inhaled therapies are preferred as well as the risks associated with long term oral steroid use. See “Allergic Rhinitis and Asthma” section for additional information.

11. **B.** One of the purposes of tocolysis is to postpone delivery long enough to allow for the maximal effect of antenatal corticosteroid administration. Tocolysis duration should be limited to 1 week and should not be initiated beyond 34 weeks. So, this patient would require tocolysis with nifedipine and antenatal steroids for lung maturity. Indomethacin use after 32 weeks is not recommended due to the risks to the fetus. See “Preterm Labor” section for additional information.

12. **B.** Since the patient has late latent syphilis, penicillin is the preferred treatment. This patient should undergo desensitization with penicillin to receive three doses of penicillin to treat the infection. See Table 99-5 in “Sexually Transmitted Infections” section for additional information.

13. **D.** Metformin and glyburide have both been used as alternatives in patients who decline insulin therapy. However, glyburide appears inferior to insulin in preventing neonatal morbidity (eg, higher NICU admission, respiratory distress, birth trauma, excessive fetal growth). See “Glucose Management” section for additional information.

14. **B.** Both labetalol and nifedipine are preferred agents to manage hypertension in pregnancy according to ACOG; however, this patient has asthma so nifedipine would be preferred. Labetalol is an alpha-1 and nonselective beta blocker, so it has the potential to constrict the beta receptors in the lungs to worse asthma control. See “Treatment of Hypertension” section for additional information.

15. **E.** High lipid solubility contributes to greater likelihood of transfer to breast milk. Drugs with a short half-life, that have low bioavailability, or are highly protein bound are less likely to pass into breast milk. See “Medication Use During Lactation” section for additional information.

Chapter 100: Menstrual-Related Disorders

Kathleen Vest; Danielle Mayer

KEY CONCEPTS

KEY CONCEPTS

①A urine pregnancy test should be one of the first steps in evaluating amenorrhea; however, the majority of primary amenorrhea cases can be attributed to either physical anomalies of the gonads, outflow tract, or anomalies of the hypothalamic–pituitary–ovarian (HPO) axis.

②For hypoestrogenic conditions associated with primary and secondary amenorrhea, estrogen (with a progestin) is recommended if correction of the underlying cause does not restore menses.

③Heavy menstrual bleeding (HMB) is generally caused by either uterine structural abnormalities or nonstructural causes.

④Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, is at the top of the differential diagnosis for any person presenting with heavy menses.

⑤The levonorgestrel intrauterine system (IUS) is associated with a 61% lower discontinuation rate and 82% fewer treatment failures when compared to other conventional pharmacotherapies for HMB.

⑥Intrauterine devices (IUD) or IUS are considered therapeutic options in a variety of menstruation-related disorders. The American College of Obstetricians and Gynecologists (ACOG) guidelines indicate that both nulliparous and multiparous females at low risk of sexually transmitted diseases are good candidates for IUS use.

⑦Abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O) is caused by oligo- or anovulation, leading to irregular, heavy menstrual bleeding due to chronic unopposed estrogen on the endometrium.

⑧Polycystic ovary syndrome (PCOS) can present as AUB-O, and symptoms include amenorrhea, oligomenorrhea, intermenstrual bleeding, and HMB. Its exact definition continues to evolve, but it is a disorder of androgen excess accompanied by ovulatory dysfunction and/or polycystic ovarian morphology. Insulin resistance is often present, and PCOS is a risk factor for the metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and possibly cardiovascular disease.

⑨Combined hormonal contraceptives (CHCs) alone should be recommended for the management of irregular menstrual cycles and clinical hyperandrogenism in adults and adolescents with PCOS.

⑩The selective serotonin reuptake inhibitors (SSRIs) are first-line pharmacologic treatment options for premenstrual dysphoric disorder (PMDD).

BEYOND THE BOOK

BEYOND THE BOOK

Watch this video about the Menstrual Cycle.

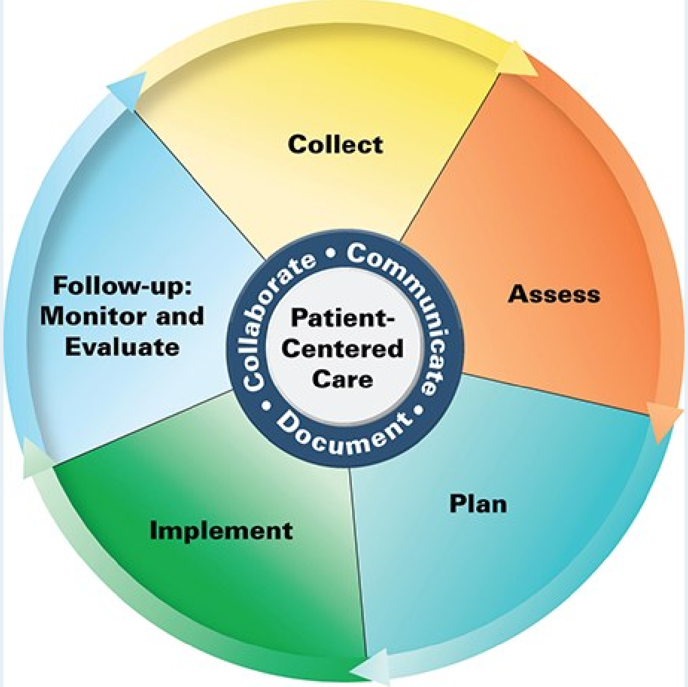
Alternatively, watch the video entitled "The Menstrual Cycle." This 9-minute video provides an overview of a normal menstrual cycle and its hormonal regulation and is useful to enhance understanding of the pathophysiology of various menstrual disorders.

Guided questions for videos:

1. Describe the major role of the following hormones in regulation of the normal menstrual cycle:
   a. GnRH
   b. LH
   c. FSH
   d. Estrogen
   e. Progesterone
2. What hormone levels are highest and lowest in the follicular phase of the normal menstrual cycle and what outcome occurs as a result?
3. What hormone levels are highest and lowest in the luteal phase of the normal menstrual cycle and what outcome occurs as a result?
4. Describe folliculogenesis. What does this term mean, in what phase of the menstrual cycle does this occur, and what hormones are most active during this process?
5. Describe the corpus luteum. What is it, in what phase of the menstrual cycle does it develop, and what hormones are most active while it is present?
6. Draw the hypothalamus–pituitary–ovarian (HPO) axis and associated hormones. Plot the negative or positive feedback loops that occur in the follicular phase, during ovulation, and in the luteal phase.

PATIENT CARE PROCESS

Patient Care Process for Menstruation-Related Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (age)
- Patient medical history
    - First day of the last menstrual cycle
    - Age of menarche
    - Cycle length and predictability
    - Number of days of each menstrual cycle, and the number of absorbent products used per day
    - History of current symptoms including relationship with menstrual cycles
    - Menstrual diary and recorded symptoms
- Social history (eg, tobacco/ethanol use), dietary and physical activity habits (especially for those with PCOS)
- Current medications including over-the-counter (OTC) nonsteroidal anti-inflammatory drug (NSAID) use, herbal products, and dietary supplements
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight
    - Labs depend on suspected underlying conditions. Common labs include follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH) (see Table 100-1). Total and free testosterone, other androgen precursors, glucose tolerance test, and fasting lipids may be obtained if PCOS is suspected. If anemia associated with heavy menstrual bleeding is suspected, obtain CBC with differential.

Assess

- Presence of severe anemia or acute bleeding that necessitates immediate treatment

- Presence of suicidal ideation associated with premenstrual dysphoric disorder that necessitates immediate psychiatric evaluation and treatment
- Whether the patient desires contraception or is attempting pregnancy
- Comorbid conditions that may affect treatment choice (eg, a nonestrogen-containing regimen should be considered in a patient with a history of deep venous thrombosis, and NSAID should not be an initial choice for a patient with a history of GI bleed).
- Acceptability of available treatment choice to the patient

Plan*

- Pharmacotherapy regimen including specific agent(s), dose, route, frequency, and duration (see Table 100-3)
- Monitoring parameters including efficacy and safety (see Table 100-4)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, invasive procedures, medication-specific information)
- Referrals to other providers when appropriate (eg, thrombosis specialist to evaluate bleeding disorders, behavioral health, dietician)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence in lifestyle interventions for individuals with PCOS

Follow-Up: Monitor and Evaluate*

- Resolution of symptoms
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate therapy as life goals change (eg, changing from desiring contraception to desiring fertility)

**Collaborate with patient, caregivers, and other healthcare professionals.*

INTRODUCTION

Problems related to the menstrual cycle are exceedingly common in females of reproductive age. This chapter discusses the most frequently encountered menstruation-related difficulties: amenorrhea; heavy menstrual bleeding (HMB); premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD), dysmenorrhea, and abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O), including polycystic ovary syndrome (PCOS). The need for effective treatments of these disorders stems from their negative impact on an individual's quality of life, reproductive health, and long-term detrimental health effects, such as increased risk of osteoporosis with amenorrhea and risk of diabetes with PCOS.

Similar to other chapters in this section, general discussions around menstruation-related disorders and their treatment are primarily framed around cisgender women. However, any individual with a female reproductive system may experience issues with menstruation. Therefore, the use of the term female is specifically meant to refer to biology, and this chapter has been written to include transgender individuals.

Before menstrual disorders are discussed, what constitutes a normal menstrual cycle needs to be considered. The American College of Obstetrics and Gynecologists recommends that clinicians ask about an individual’s first day of the patient's last menstrual period, as well as the pattern of menses, during every clinical encounter.[1] Identification of menstrual patterns should begin in adolescence, which may improve the early detection of potential health concerns.[1] Before menstrual disorders are discussed, what constitutes a normal menstrual cycle for the individual needs to be considered.

In adolescents, immaturity of the hypothalamic–pituitary–ovarian axis in the early years after menarche may lead to longer cycles due to anovulation.[1] However, 90% of these cycles will be within the range of 21 to 45 days.[1] The following menstrual characteristics and patterns are considered normal:[1]

- Median age of menarche of 12.4 years, and menarche by age 15
- Menstrual cycle interval between 21 and 45 days
- Menstrual flow length 7 days or less
- Menstrual product use between 3 to 6 pads or tampons per day

In adult females not using hormonal contraception, a normal menstrual period lasts between 4.5 and 8 days, and cycle lengths range from 24 to 28 days.[2] Normal variation in cycle length is considered to be 7 to 9 days, depending on a patient's age: 18 to 25 years ≤ 9 days, 26 to 41 ≤ 7 days, 42 to 45 ≤ 9 days.[3] Blood loss between 5 and 80 mL during each period is considered normal.[2]

AMENORRHEA

Epidemiology

Amenorrhea is defined as no menstrual bleeding in a 90-day period,[2] and can be either primary or secondary in nature. Primary amenorrhea is the absence of menses by age 15 years in females who have never menstruated.[4] Secondary amenorrhea is the absence of menses for three cycles or for 6 months in a previously menstruating individual.[4,5]

Primary amenorrhea occurs in less than 0.1% of the general population. Secondary amenorrhea, in comparison, has an incidence of 3% to 4% in the general population and occurs more frequently in individuals younger than 25 years with a history of menstrual irregularities and in those involved in competitive athletics.[6]

Etiology

In two-thirds of females, menses occur generally at 28 ± 3 days, and cycle lengths of 18 to 40 days are considered within the normal range.[5] Amenorrhea is not itself a diagnosis, but a sign of a disorder.[5] There are three broad categories of amenorrhea etiology:

- Anatomical causes, including pregnancy and uterine structural abnormalities
- Endocrine disturbances leading to chronic anovulation
- Ovarian insufficiency/failure

① While a urine pregnancy test is one of the first steps in evaluating amenorrhea, the majority of primary amenorrhea cases can be attributed to either anomalies involving (i) the hypothalamic–pituitary axis resulting in endocrine disturbances, (ii) ovarian function, or (iii) outflow tract.[7] Similarly, greater than 50% of secondary amenorrhea cases are due to the impact of disturbances of the hypothalamic–pituitary–adrenal (HPA) axis or the hypothalamic–pituitary–ovarian (HPO) axis.[6] Therefore, in organizing an approach to diagnosis and treatment, it is helpful to consider the organ systems involved in the menstrual cycle, which include the uterus, ovaries, anterior pituitary, and hypothalamus.

Pathophysiology

Ovulation is required for the follicle (an estrogen-secreting body) to become a corpus luteum (a progesterone-secreting body). Without ovulation, the proper sequence of estrogen production, progesterone production, and estrogen/progesterone withdrawal will not occur. This can result in amenorrhea. Anovulation can occur secondary to endocrine disturbances or ovarian insufficiency.

Each organ in the HPO axis, along with the uterus, is of importance in determining amenorrhea's etiology and pathophysiology. Beginning with the uterus/outflow tract and progressing caudally will result in a comprehensive differential diagnosis. However, coexisting physical signs and symptoms, and a thorough history, typically help the clinician prioritize evaluation steps. Table 100-1 lists the pathophysiology of amenorrhea relative to the organ system(s) involved and the specific condition(s) that results in amenorrhea.

TABLE 100-1

Pathophysiology of Selected Menstrual Bleeding Disorders

Organ System	Condition	Pathophysiology/Laboratory Findings
Amenorrhea		
Uterus	Asherman's syndrome	Postcurettage/postsurgical uterine adhesions
	Congenital uterine abnormalities	Abnormal uterine development
Ovaries	Turner's syndrome	Lack of ovarian follicles
	Gonadal dysgenesis	Other genetic abnormalities
	Premature ovarian failure	Early loss of follicles
	Chemotherapy/radiation	Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma	↑ Prolactin suppresses the HPO axis
	Hypothyroidism	TRH causes ↑ prolactin, other abnormalities
	Medication (antipsychotics, verapamil)	↑ Prolactin suppresses the HPO axis
Hypothalamus	FHA	↓ Pulsatile GnRH secretion in the absence of other abnormalities
	Eating disorder	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss
	Exercise	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat
	Anovulation/PCOS	Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
Abnormal Uterine Bleeding Associated with Ovulatory Dysfunction (AUB-O)		
Physiologic causes	Adolescence	Immaturity of the HPO axis: no LH surge
	Perimenopause	Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation (PCOS)	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance

	Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss)	Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH
	Hyperprolactinemia (pituitary gland tumor, psychiatric medications)	High prolactin
	Hypothyroidism	High TSH
	Premature ovarian failure	High FSH
Heavy Menstrual Bleeding (HMB)		
Hematologic	von Willebrand disease	Factor VII defect causing impaired platelet adhesion and increased bleeding time
	Idiopathic thrombocytopenic purpura	Decrease in circulating platelets, can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in the HPO axis
Uterine	Fibroids	Alteration of endometrium, changes in uterine contractility
	Adenomyosis	Alteration of endometrium, changes in uterine contractility
	Endometrial polyps	Alteration of endometrium
	Gynecologic cancers	Various dysplastic alterations of endometrium, uterus, cervix

FHA, functional hypothalamic amenorrhea; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic–pituitary–ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary syndrome; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone.

Data from References [4-9].

Uterus/Outflow Tract

For menstruation to occur, a uterus, functional endometrium, and patent vagina must be present. Several anatomic abnormalities may cause amenorrhea.[7] Congenital anomalies such as imperforate hymen or uterine agenesis may be discovered by physical examination. An acquired condition of the genital tract, such as Asherman's syndrome or cervical stenosis, is more likely in secondary amenorrhea.

Ovaries

Normal ovarian function is critical for menstruation to occur. The ovaries must respond appropriately to follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by secreting estrogen and progesterone in the proper sequence to influence endometrial growth and shedding (Fig. 100-1).

FIGURE 100-1

Hormonal fluctuations with the normal menstrual cycle. (FSH, follicle-stimulating hormone; LH, luteinizing hormone.)

Primary ovarian insufficiency occurs when potentially viable primordial follicles in the ovaries have been depleted.[9] Estrogen production from the remaining ovarian follicles is insufficient to stimulate endometrial growth in the absence of follicles. The etiologies for primary ovarian insufficiency include bilateral oophorectomy,[10] genetic anomalies,[9] autoimmunity, and iatrogenic causes as a result of radiation or chemotherapy.[11] However, in 90% of cases, the cause cannot be identified.[9]

Pituitary Gland

The anterior pituitary gland secretes FSH and LH in sequential fashion in response to hypothalamic stimulation and a complex ovarian feedback mechanism. Normal secretion of FSH and LH is altered by several endocrinologic and iatrogenic conditions, including thyroid disease, hyperprolactinemia, and dopaminergic medication administration.

Hypothalamus

The hypothalamus secretes cyclic gonadotropin-releasing hormone (GnRH), which causes the pituitary to produce FSH and LH. Disrupting this cyclic process interrupts the hormonal cascade that results in normal menstruation. Anorexia nervosa, bulimia, intense exercise, and stress may cause hypothalamic amenorrhea, known as functional hypothalamic amenorrhea (FHA). Further, research has confirmed the role of leptin insufficiency in causing hypogonadotropic hypogonadism leading to hypothalamic amenorrhea.[12]

Amenorrhea Clinical Presentation

CLINICAL PRESENTATION: Amenorrhea

General

- Although patients may be concerned about the cessation of menses and implications for fertility, patients are generally not in acute physical distress.

Symptoms

- Patients will note cessation of menses.
- Patients may complain of infertility, vaginal dryness, or decreased libido.

Signs

- Cessation of menses for more than 6 months in individuals with established menstruation, absence of menses by age 16 in the presence of normal secondary sexual development, or absence of menses by age 14 in the absence of normal secondary sexual development.
- Recent significant weight loss or weight gain.
- Presence of acne, hirsutism, hair loss, or acanthosis nigricans may suggest androgen excess.

Laboratory Tests

- Pregnancy test
- Serum FSH and LH
- Thyroid-stimulating hormone
- Prolactin
- If hyperandrogenic state (eg, PCOS) is suspected, consider free and total testosterone, dehydroepiandrosterone, fasting glucose, and fasting lipid panel

Other Diagnostic Tests

- Progesterone challenge to confirm functional anatomy and adequate estrogenization.
- Pelvic ultrasound to evaluate for polycystic ovaries, presence/absence of uterus, and/or structural abnormalities of the reproductive tract organs.

Treatment

Desired Outcomes

In general, the treatment options for amenorrhea depend on its causes. Therapeutic modalities for amenorrhea should ensure the occurrence of normal puberty and restore the menstrual cycle. Treatment goals include bone density preservation, bone loss prevention, and ovulation restoration to improve fertility if desired. Hypoestrogenism may affect quality of life via hot flash induction (premature ovarian failure), dyspareunia, and, in prepubertal females, lack of secondary sexual characteristics and absence of menarche. Treatment is targeted at reversing these effects.

General Approach to Treatment

The overall success of any intervention to treat amenorrhea depends on proper identification of the disorder's underlying cause(s). Once the cause is identified, the appropriate intervention(s) can be made. For patients experiencing amenorrhea secondary to hypoestrogenic states, a diet rich in calcium and vitamin D is essential to minimize any negative impact on bone health.

Nonpharmacologic Therapy

Nonpharmacologic therapy for amenorrhea varies depending upon the underlying cause. Amenorrhea secondary to anorexia may respond to weight gain. In young individuals for whom excessive exercise is an underlying cause, reduction of exercise quantity and intensity are important. Evaluation for a possible eating disorder may be appropriate (see Chapter e83 “Eating Disorders,” for more information). Cognitive behavioral therapy has been shown to restore ovarian function in individuals with FHA.[13] In 2017, the Endocrine Society Clinical Practice Guideline recommended a reasonable trial of psychological, nutrition, and/or modified exercise intervention prior to use of pharmacotherapy in patients with FHA.[14] In medication-induced hyperprolactinemia (Table 100-2),[15] the clinician may consider alternative agents that do not inhibit dopamine receptors or increase prolactin levels.

TABLE 100-2

Medications That May Induce Hyperprolactinemia

Medication Class	Agents
First-generation antipsychotics	Phenothiazines (eg, prochlorperazine, chlorpromazine)
	Butyrophenones (eg, haloperidol)
	Thioxanthenes (eg, chlorprothixene)
Second-generation antipsychotics	Risperidone
	Molindone
Antidepressants	Clomipramine
Monoamine oxidase inhibitors	Pargyline
	Clorgyline
Antihypertensives	Verapamil
Gastrointestinal promotility agents	Metoclopramide
	Domperidone

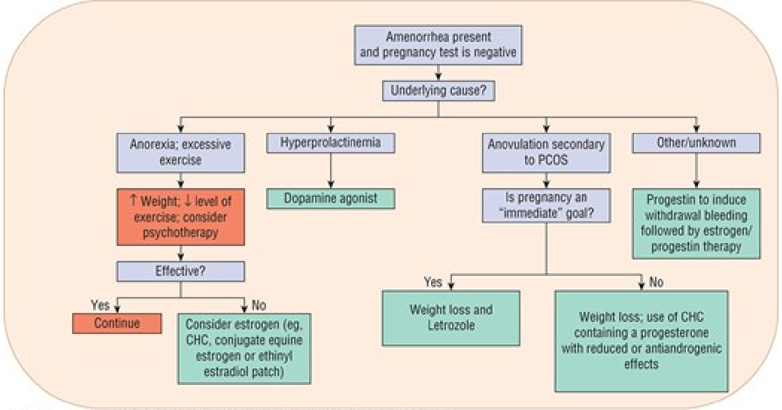
Data from Reference [15].

Pharmacologic Therapy

② For hypoestrogenic conditions associated with primary or secondary amenorrhea, historically estrogen has been supplemented as an oral contraceptive, conjugated equine estrogen, or estradiol patch, in conjunction with progestin in an attempt to decrease osteoporosis risk. However, data supporting estrogen supplementation in FHA are based on a limited number of studies with small sample size and short follow-ups.[16] Therefore, the primary approach for FHA should be the correction of energy balance to restore HPO axis function.[16] The 2017 Endocrine Society Clinical Practice Guideline for FHA recommends the short-term use of transdermal estradiol with cyclic oral progestins, after an adequate trial of nonpharmacological therapy (eg, psychological and nutritional intervention).[14] Combined hormonal contraceptives (CHC) and synthetic ethinyl estradiol are no longer recommended as first-line agents for patients with FHA.[14] However, CHCs are also useful for pregnancy prevention, treatment of acne, and other conditions in this population.[14] For individuals with primary ovarian insufficiency, a prospective study with estradiol 100 mcg/day transdermal patch suggested improvement in bone mineral density to normal population values.[17] Table 100-3 lists therapeutic agents for amenorrhea treatment, including recommended doses. Figure 100-2 illustrates a treatment algorithm for the management of amenorrhea.

FIGURE 100-2

Treatment algorithm for amenorrhea. (CHC, combined hormonal contraceptive; PCOS, polycystic ovary syndrome.)



Amenorrhea present and pregnancy test is negative
Underlying cause?
Anorexia; excessive exercise
Hyperprolactinemia
Anovulation secondary to PCOS
Other/unknown
↑ Weight; ↓ level of exercise; consider psychotherapy
Dopamine agonist
Is pregnancy an "immediate" goal?
Progestin to induce withdrawal bleeding followed by estrogen/ progestin therapy
Effective?
Yes
No
Continue
Consider estrogen (eg, CHC, conjugate equine estrogen or ethinyl estradiol patch)
Yes
No
Weight loss and Letrozole
Weight loss; use of CHC containing a progesterone with reduced or antiandrogenic effects

TABLE 100-3

Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorder(s)	Agent(s)	Brand Name(s)	Usual Recommended Dose
Amenorrhea (primary or secondary)	CEE	Premarin, Cenestin, Enjuvia	0.625-1.25 mg by mouth daily on days 1-25 of the cycle
	Ethinyl estradiol patch	Alora, Climara, Vivelle-Dot	50 mcg/24 hr
	CHC	Various	30-40 mcg formulations
Amenorrhea (secondary)	Oral MPA	Provera	5-10 mg by mouth on days 14-25 of the cycle
	Progesterone vaginal gel	Crinone	1.125 g of 4% gel intravaginally every other day for 6 doses; if no response, increase to 8% gel for 6 doses
	Norethindrone	Aygestin	5 mg by mouth daily for 7-10 days
	Micronized progesterone	Prometrium	400 mg by mouth daily for 7-10 days
Amenorrhea related to	Bromocriptine	Parlodel, Cycloset	2.5-15 mg daily in 2 to 3 divided doses

hyperprolactinemia			
	Cabergoline	Dostinex	0.25-2 mg by mouth once weekly or in 2 divided doses
Anovulatory bleeding	CHC	Cyred 28, Emoquette 28, Yasmin 28, Yaz, Beyaz, and others	≤35 mcg ethinyl estradiol
Dysmenorrhea	CHC	• Examples include: Norgestrel containing: Cryselle 28, Low-Ogestrel, Levonorgestrel containing: Levora 28, Camrese, Aviane 28, Lessina 28 • Other progestins: Sprintec 28, Yasmin 28, Yaz Extended-cycle: Introvale, Setlakin, Seasonale, Seasonique, LoSeasonique	<35 mcg formulations; use of extended-cycle formulations may be beneficial for this indication
	Injectable MPA	Depo-Provera, Depo-SubQ Provera 104	150 mg intramuscularly or 104 mg subcutaneously every 12 weeks
	LNG-IUS	Mirena	20 mcg released daily
	NSAIDs (any are acceptable); the most commonly studied/cited are included in this table	Ibuprofen (Motrin, Advil),	Ibuprofen 800 mg by mouth initially, followed by 400-800 mg every 8 hr as needed
		Naproxen (Naprosyn)	Naproxen 440-550 mg by mouth initially, followed by 220-550 mg every 12 hr as needed
		Mefanamic acid	500 mg by mouth initially, followed by 250 mg every 6 hr as needed
		Celecoxib (Celebrex)	400 mg by mouth initially, followed by 200 mg every 12 hr as needed
Heavy menstrual bleeding	CHC	Various Estradiol valerate/dienogest (Natazia)	Optimal dose unknown
	LNG-IUS	Mirena	20 mcg released daily
	Oral MPA	Provera	5-10 mg by mouth on days 5-26 of the cycle or during the luteal phase
	Tranexamic acid	Lysteda	1,300 mg by mouth every 8 hr once heavy bleeding begins; dose for 4-7 days as needed per cycle
Heavy menstrual bleeding associated with uterine	Elagolix/estradiol/norethindrone acetate plus elagolix	Oriahnn	Elagolix 300 mg/estradiol 1 mg/norethindrone acetate 0.5 mg) in the morning and elagolix 300 mg in the evening for up to 24 months

fibroids			
PCOS-related amenorrhea and/or AUB-O	Injectable MPA CHC	Depo-Provera, Depo-SubQ Provera 104 Desogestrel containing: Cyred 28, Cred EQ 28 Norgestimate containing: Tri-Lo, Sprintec Drospirenone containing: Yasmin 28, Yaz, Beyaz	150 mg intramuscularly or 104 mg subcutaneously every 12 weeks ≤30 mcg ethinyl estradiol with either desogestrel, norgestimate, or drospirenone
	Oral MPA	Provera	10 mg by mouth for 10 days
	Metformin	Glumetza	1,500-2,000 mg by mouth daily
PMDD	Clomipramine	Anafranil	25-75 mg by mouth daily taken either continuously or only during the luteal phase
	Drospirenone	Yasmin 28, Yaz, Beyaz	3 mg (+ ≤30 mcg ethinyl estradiol) by mouth on days 1-21 of the menstrual cycle
	Leuprolide	Lupron Depot	3.75 mg intramuscularly
PMDD	SSRIs	Citalopram, escitalopram, fluoxetine (Sarafem or Prozac), paroxetine, sertraline	Citalopram 10-30 mg; escitalopram 10-20 mg; fluoxetine 10-20 mg; fluvoxamine 50 mg; paroxetine 10-30 mg; sertraline 25-150 mg; all agents are given by mouth daily and can be dosed either continuously or during the luteal phase only
	SNRIs	Venlafaxine (IR and XR), duloxetine	Venlafaxine 50-200 mg, can be dosed continuously or during the luteal phase only; duloxetine 60 mg dosed continuously

CEE, conjugated equine estrogen; LNG-IUS, levonorgestrel intrauterine system; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal anti-inflammatory drug; CHC, combined hormonal contraceptive; PCOS, polycystic ovary syndrome; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitors; SNRI, serotonin–norepinephrine reuptake inhibitors.

Data from References [3,4,7,8,14,18-36].

When hyperprolactinemia is the cause of amenorrhea, dopamine agonists such as bromocriptine and cabergoline aid in reducing prolactin concentrations and the resumption of menses. Bromocriptine normalizes prolactin levels in 58% of affected patients, while cabergoline has the same effect in 85%.[14]

Progestins induce withdrawal bleeding in those with secondary amenorrhea, and Table 100-3 outlines the doses for various progestins. Absence of withdrawal bleeding after a progestin challenge may suggest outflow tract obstruction or insufficient endometrial estrogen exposure.[14]

Progestin efficacy for secondary amenorrhea varies by formulation used. Progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate (MPA) induces withdrawal bleeding in 95% of treated patients.[37] Table 100-3 identifies the types and doses of progestins used for secondary amenorrhea treatment, and Fig. 100-2 illustrates when to consider progestin use for amenorrhea treatment.

Amenorrhea related to PCOS-induced anovulation is discussed subsequently in the “abnormal uterine bleeding” section.

Adolescents

Amenorrhea in the adolescent population is of concern because developmentally this is the time when peak bone mass is achieved. The cause of amenorrhea, whether primary or secondary, must be promptly identified, as amenorrhea and its related hypoestrogenism negatively affect bone development. In addition to treating or eliminating amenorrhea's underlying cause, ensuring that the patient is receiving adequate amounts of calcium and vitamin D is imperative. Estrogen replacement is important for bone health.

Evaluation of Therapeutic Outcomes

Table 100-4 identifies the mechanisms of action, expected outcomes, and monitoring parameters for pharmacologic agents used for amenorrhea management.

TABLE 100-4

Pharmacologic Properties and Monitoring Parameters for Select Agents or Classes of Medications Used in the Management of Menstrual Disorders

Therapeutic Agent or Medication Class	Mechanism of Action/Role in Particular Menstrual Disorders	Adverse Medication Reactions	Monitoring for Expected Outcomes of Specific Menstrual Disorders	Comments
Dopamine agonists (bromocriptine and cabergoline)	Suppresses prolactin production from pituitary tumors such that resumption of normal FSH and LH production occurs	Hypotension, nausea, constipation, anorexia, Raynaud's phenomenon, fatigue, headache	Amenorrhea related to hyperprolactinemia: Baseline and weekly prolactin levels should be measured with dosage increases until resumption of menses is observed. Continue therapy for 6-12 months following return of menses and continued normalization of serum prolactin levels	Inhibits CYP3A4 and is metabolized by CYP3A4 St John's Wort induces CP3A4; coadministration may lead to treatment failure
Tricyclic antidepressants (clomipramine)	PMDD: Exact mechanism unknown	Dry mouth, constipation, fatigue, vertigo, sweating	Reduction in or absence of initial symptoms and improved quality of life within 1-3 menstrual cycles of therapy	
Oral combined hormonal contraception (CHC)	• Exogenous estrogen and progesterone that suppresses FSH and LH production and thus inhibits ovulation • Can be used to reduce menstrual flow (menorrhagia, dysmenorrhea), and control menstrual cycle (anovulatory bleeding secondary to hypoestrogenism)	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, GI upset, headache, peripheral edema	• Amenorrhea: Resumption of menses within 1-2 months of therapy • Anovulatory bleeding: Improvement in pattern of abnormal bleeding within 1-2 months of therapy • Dysmenorrhea: Reduction in or absence of pelvic pain within 1-2 months of therapy • Menorrhagia: Reduction in blood loss with menses over 1-2 months of therapy. Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline	St John's Wort contributes to altered menstrual bleeding. Rifampin induces estrogen metabolism, possibly contributing to treatment failure. Sulfa-containing medications may contribute to increased photosensitivity

Conjugated equine estrogen (CEE)	Estrogen replacement for hypoestrogenic states leading to anovulatory bleeding	As noted for oral CHC	Anovulatory bleeding: Improvement in pattern of abnormal bleeding within 1-2 months of therapy	Same as oral CHC
Drospirenone-containing CHCs	Progesterone with antimineralocorticoid and antiandrogenic properties; decreases emotional lability associated with PMDD	As noted for oral CHC; increased risk of hyperkalemia	PCOS-related amenorrhea or anovulatory bleeding: in addition to the improvement in the pattern of abnormal bleeding within 1-2 months of treatment, patients should also experience an improvement in androgen-excess symptoms such as acne/oily skin and hirsutism	Same as oral CHC Coadministration of potassium-sparing diuretics or diets high in potassium may contribute to increased serum potassium concentrations, particularly in patients with renal dysfunction
Ethinyl estradiol transdermal patch	Same as combination oral CHC and CEE	As noted for oral CHC; however, lesser effects on serum cholesterol concentrations because patch avoids first-pass metabolism	Amenorrhea: Resumption of menses within 1-2 months of therapy	Same as oral CHC
Leuprolide	GnRH agent that contributes to suppression of FSH and LH and ultimately a reduction in estrogen and progesterone, inhibiting the normal menstrual cycle/hormonal fluctuations	Hot flashes, night sweats, headache, nausea	PMDD: Improvement in PMDD signs and symptoms within 1-2 months of therapy	
Levonorgestrel intrauterine system (LNG-IUS)	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Irregular menses, amenorrhea	• Dysmenorrhea: Reduction in or absence of pelvic pain after 1-2 months of therapy • Menorrhagia: Reduction in blood loss with menses over 1-2 months of therapy. Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline	
Medroxyprogesterone acetate (MPA) (oral and injectable)	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual	Edema, anorexia, depression, insomnia, weight gain or loss,	• Dysmenorrhea: Reduction in or absence of pelvic pain after 1-2 months of therapy • Menorrhagia: Reduction in blood	

	growth of the endometrium	increase in serum total and LDL cholesterol, may reduce HDL cholesterol	loss with menses over 1-2 months of therapy. • Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline • PCOS-related amenorrhea and/or anovulatory bleeding: Resumption of menses over 1-2 courses of therapy	
Metformin	Inhibits hepatic glucose production and increases sensitivity of tissues to insulin, thus reducing insulin resistance	Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis (rare)	PCOS-related amenorrhea and/or anovulatory bleeding: If desired, monitor for ovulation after 3-6 months of therapy	IV contrast dye may increase the risk of lactic acidosis; stop metformin 1 day prior and restart when renal function is normal and stabilized following the IV dye
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Inhibits prostaglandin release that occurs with menses, thus reducing inflammatory response contributing to dysmenorrhea	GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness	Dysmenorrhea: Reduction in or absence of pelvic pain within hours of initiating Menorrhagia: Reduction in blood loss with menses over 1-2 months of therapy	
Selective serotonin reuptake inhibitors (SSRIs)	Exact mechanism in PMDD unknown	Sexual dysfunction (reduced libido, anorgasmia), insomnia, sedation, hypersomnia, nausea, diarrhea	Improvement in PMDD signs and symptoms observed within 1-3 months of therapy	
Tranexamic acid	Antifibrinolytic effects by reversibly blocking lysine binding sites on plasminogen, preventing fibrin degradation and a reduction in menstrual blood loss	Nausea, vomiting, diarrhea, dyspepsia	Menorrhagia: Reduction in blood loss with menses should be noticeable with the first month of therapy Improvement in hemoglobin/hematocrit after 3 months of therapy compared to baseline	
Venlafaxine	Exact mechanism in PMDD unknown		Improvement in PMDD signs and symptoms observed within 1-3 months of therapy	

CEE, conjugated equine estrogen; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LH, luteinizing hormone; LNG-IUS, levonorgestrel intrauterine system; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal anti-inflammatory drug; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

HEAVY MENSTRUAL BLEEDING

Epidemiology

Heavy menstrual bleeding (HMB) is the term now used in place of menorrhagia.[41] The classical definition, however, remains the same: menstrual blood loss greater than 80 mL per cycle or menstrual bleeding lasting greater than 7 days per cycle.[38] This definition has been questioned because of difficulty quantifying menstrual loss in clinical practice. Additionally, many individuals with “heavy menses” but whose blood loss is less than 80 mL merit treatment consideration because of flow containment issues, unpredictably heavy flow days, or other associated symptoms.[23,42] Diagnosis has also been considered based upon the impact of HMB on quality of life and social, professional, familial, or sexual roles.

HMB is one of the most commonly encountered gynecological problems, accounting for 18% to 30% of gynecologic visits.[25] HMB affects an individual's physical, psychological, and social function. The amount of blood loss may make it impractical or embarrassing to leave home for fear of soiling outer garments, leading to decreased work productivity and limited social activities.[25]

Etiology

③ ④ The International Federation of Gynecology and Obstetrics Menstrual Disorders Working Group created the PALM-COEIN classification system to define the causes of abnormal uterine bleeding (AUB).[43] The PALM group of classification includes structural causes of AUB: **P**olyp, **A**denomyosis (endometrial tissue within the myometrium), **L**eiomyoma (also known as Fibroids), and **M**alignancy.[43] The COEIN components include nonstructural causes: **C**oagulopathy, **O**vulatory disorders, and **E**ndometrial disorders, **I**atrogenic causes and **N**ot classified.[43] Combined the PALM-COEIN classification also characterizes intermenstrual bleeding as bleeding that occurs between predictable and clearly cyclic menses, while AUB is defined as bleeding that is abnormal in either regularity, timing, or volume.[25,43] Under these definitions, HMB specifically refers to an abnormally excessive volume of menstrual bleeding that affects the individual’s quality of life. Causes of HMB may include AUB due to polyps (AUB-P), adenomyosis (AUB-A), leiomyoma (AUB-L), as well as nonstructural causes such as coagulopathy (AUB-C), and endometrial dysfunction (AUB-E).[25] Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis list for any patient presenting with heavy menses.[12] Bleeding disorders including von Willebrand disease, symptomatic hemophilia, platelet dysfunction, and Factor VIII and IX deficiencies must also be considered as these were found to exist in 20% of patients with HMB.[19] Hypothyroidism also may be associated with heavy menses.[19,41] Additionally, uterine structural abnormalities, such as polyps, adenomyosis, and leiomyoma, are not uncommon in those with HMB,[25] with fibroids, specifically, being identified in as many as 40% of patients with HMB.[28]

Pathophysiology

HMB may be the result of one of several very diverse causes including hematologic, hepatic, endocrine, and/or uterine disorders. Table 100-1 lists the pathophysiology of HMB relative to the organ system(s) involved and the specific conditions that may result in HMB.

Heavy Menstrual Bleeding Clinical Presentation

CLINICAL PRESENTATION: Heavy Menstrual Bleeding

General

- Patients may or may not be in acute distress.

Symptoms

- Patients may complain of heavy/prolonged menstrual flow. They also may have signs of fatigue and lightheadedness in cases of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs

- Orthostasis, tachycardia, and pallor may be noted in cases of significant anemia or acute blood loss.

Laboratory Tests

- Complete blood count and ferritin levels; hemoglobin and hematocrit results may be low.
- If the history dictates, testing (eg, prothrombin time, activated partial thromboplastin time, international normalized ratio, von Willebrand factor antigen, Factor VIII, factor IX activity) may be performed to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging
- Papanicolaou (Pap) smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

Treatment

Desired Outcomes

The primary goal of treatment for HMB is to reduce menstrual flow. Along with this, treatments should be initiated to improve the patient's quality of life, and defer the need for surgical intervention.

General Approach to Treatment

As several treatment options exist for HMB, the choice regarding which specific agent to use depends on the patient's treatment history, concomitant concerns, and the adverse medication effect profile for the various agents.

Nonpharmacologic Therapy

Nonpharmacologic interventions for HMB include surgical procedures generally reserved for patients not responding to pharmacologic treatment. These interventions vary from conservative endometrial ablation to hysterectomy.[25,42]

Pharmacologic Therapy

While surgical treatment may be an option for HMB, effective medical treatments are recommended as the initial treatment choice. Estrogen is the recommended treatment for managing acute severe bleeding episodes in patient's without suspected or known bleeding disorders.[44] Following its initial use to control acute bleeding episodes, therapy continuation may be necessary to prevent future occurrences. Both estrogen-containing CHCs and progestin-only regimens can be used for maintenance therapy.[25] Although it is assumed that all CHCs will reduce menstrual blood loss, the only agent that has been FDA approved is a combination of estradiol valerate and dienogest.[25] Table 100-2 identifies the variety of pharmacologic treatment options and their recommended dosing for HMB management.

Among the agents used to treat HMB, the nonsteroidal anti-inflammatory drugs (NSAIDs) have the advantage of administration only during menses and are associated with a 10% to 51% reduction in blood loss.[25] For individual's desiring to avoid pregnancy, CHC should be considered as a 30% to 60% reduction in menstrual blood loss has been observed.[25] The 1-year continuation rates of CHCs in individuals with HMB range from 72% to 84%.[25] The best studied CHC option for HMB and the only agent approved by the FDA for the indication of HMB is the four-phasic formulation containing estradiol valerate and dienogest.[24,25]

For those with contraindications to CHCs, progestin-only methods induce amenorrhea and reduce menstrual blood loss.[25] Cyclic progesterone therapy for 14 days, administered as oral norethindrone acetate or medroxyprogesterone acetate, reduces menstrual blood loss in only 2% to 30% of patients.[25] However, when administered as long course (for 21 days, starting on day 5 after onset of menses), they reduce menstrual blood loss in 63% to 78% of patients.[25]

Another progestin-only treatment option for HMB is the levonorgestrel-releasing intrauterine system (LNG-IUS). This is considered the most effective treatment to reduce menstrual flow.[25] In particular, a 70% to 96% reduction in blood loss has been observed with its use,[25] and its use has also resulted in postponing or canceling scheduled endometrial ablation surgery or hysterectomy.[40] Among those using this treatment option, only 9% eventually opted for surgery.[40] Further, its therapeutic efficacy is similar to endometrial ablation up to 2 years following treatment.[29]

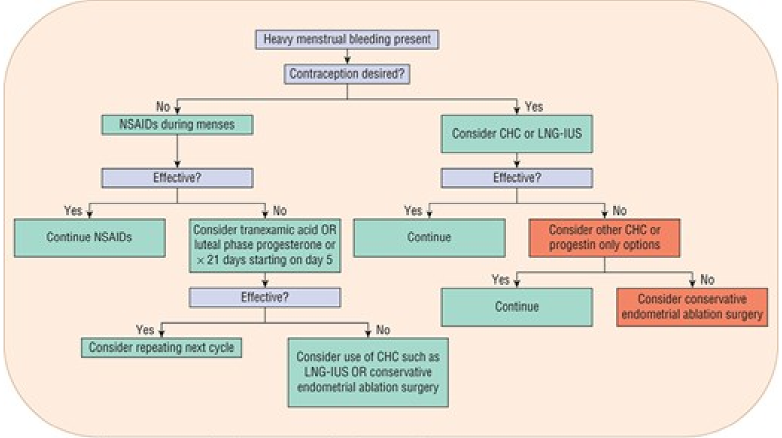
Tranexamic acid is also approved in the United States for primary HMB treatment. Its use is associated with 34% to 56% reduction in menstrual blood loss.[25] Compared to many of the other options, its use may be preferable among those desiring pregnancy or in whom hormonal therapy may not be appropriate.

⑤ For individuals in whom pregnancy is not an immediate goal, it is reasonable to start with either a CHC or the LNG-IUS. While either choice is acceptable for both nulligravid and multiparous patients who desire a long-term reversible form of contraception, cost-effectiveness data suggest LNG-IUS is the best first-line choice for those desiring contraception.[28,42] Clinical trial data illustrate a higher failure rate with the oral CHCs (32%) compared to the LNG-IUS (11%) as the primary treatment method.[28] When compared to other conventional medical therapies used for HMB, the LNG-IUS is associated with a 61% lower discontinuation rate and 82% fewer treatment failures.[26]

For those who have HMB associated with ovulatory cycles and do not desire hormonal therapy and/or contraception, NSAIDs during menses is a reasonable choice in the absence of any contraindications or GI disorders such as peptic ulcer disease or gastroesophageal reflux disease. This choice is convenient (only taken during menses) and comparatively inexpensive. Given their adverse effects, reduced efficacy compared to the first-line agents, and/or cost, use of oral progesterone, and depot MPA should be reserved. Tranexamic acid is another treatment option that can be taken only during menses.[25] Figure 100-3 presents an algorithm for HMB treatment.

FIGURE 100-3

Treatment algorithm for HMB. (CHC, combined hormonal contraceptive; LNG-IUS, levonorgestrel-releasing intrauterine system; NSAIDs, nonsteroidal anti-inflammatory drugs)



Heavy menstrual bleeding present
Contraception desired?
No
Yes
NSAIDs during menses
Consider CHC or LNG-IUS
Effective?
Effective?
Yes

For patients with HMB associated with uterine fibroids a new oral agent, Elagolix/estradiol/norethindrone acetate and elagolix (Oriahnn), was approved in June 2020.[44] Elagolix is a novel non-peptide oral, short-acting gonadotropin-releasing hormone (GnRH) receptor antagonist dosed as one capsule containing elagolix 300 mg, estradiol 1 mg, and norethindrone 0.5 mg in the morning and one capsule containing elagolix 300 mg in the evening.[45,46] Based on data from phase three clinical trials, subgroup analyses, and extension studies, it is reasonable to consider Elagolix/estradiol/norethindrone acetate and elagolix as an oral option for the management of HMB associated with uterine fibroids.[46-48] There are some clinical relevant safety considerations that may limit the use of this agent in some patient populations. One of the primary concerns is the risk of potentially irreversible BMD loss due to estrogen blockade.[45] As a result, use should be limited to 24 months. It is also contraindicated in individuals with existing cardiovascular disease or at high risk of a cardiovascular event.[45] Individuals taking this medication must also utilize non-hormonal contraception for the duration of treatment, as pregnancy is contraindicated with therapy.[45,46]

Special Populations

⑥ Although it was believed IUS use should be avoided in nulliparous patients, guidelines from the American College of Obstetricians and Gynecologists (ACOG) indicate that both multiparous and nulliparous females (including adolescents) at low risk of sexually transmitted infections are good candidates for intrauterine system (IUS) use.[49] Therefore, any of the treatments discussed (including the LNG-IUS) are options in those presenting with HMB.

Dosage adjustment for tranexamic acid is recommended for reduced renal function. Patients with serum creatinine between 1.4 and 2.8 mg/dL (124 and 252 μmol/L) should receive only 1,300 mg by mouth twice daily; those with serum creatinine between 2.9 and 5.7 mg/dL (253 and 504 μmol/L) should receive 1,300 mg by mouth once daily; those with serum creatinine above 5.7 mg/dL (504 μmol/L) should receive 650 mg by mouth once daily. Additionally, due to its potential to increase the risk for venous thromboembolism, it should be used with extreme caution in individuals with a history of thrombosis and should not be combined with estrogen-containing contraceptives.

Evaluation of Therapeutic Outcomes

Table 100-3 identifies the significant pharmacologic properties of agents used for the management of HMB, the expected outcomes for each agent, and specific monitoring parameters for the treatment modalities used in HMB management.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Epidemiology

Premenstrual syndrome (PMS) is represented by a cyclic pattern of symptoms (Table 100-5) occurring in the late luteal phase of the menstrual cycle that resolve at the onset of menses. Up to 80% of menstruating patients experience PMS symptoms.[31] However, most do not report impairment of their daily activities.[31] There have been over 100 symptoms reported by patients with PMS and they will often present differently, thus requiring an individualized treatment plan. Charting symptoms is helpful for the patient and clinician to identify the symptoms, severity, and patterns in which they occur as well as response to treatment. Diagnosis requires that at least one moderate-to-severe somatic or psychiatric symptom is present in the last week of the luteal phase for at least 3 months.[32,50]

TABLE 100-5

Symptoms Often Reported with Premenstrual Syndrome

At least one of the following somatic or affective symptoms should be present during the 5 days before menses in the last three menstrual cycles			
Somatic symptoms		**Affective symptoms**	
- Abdominal bloating - Breast swelling or tenderness - Headache Muscle or joint pain - Swelling of extremities - Weight gain - Fatigue - Dizziness	- Nausea/vomiting - Acne - Pelvic pressure/heaviness - Constipation or diarrhea - Menstrual migraines - Appetite changes	- Angry outbursts - Anxiety - Depression - Difficulty in concentration - Confusion - Irritability - Social withdrawal - Forgetfulness	- Sadness - Tension - Tearfulness - Restlessness - Loneliness - Food cravings - Change in libido

Data from Reference [32].

Some patients experience severe mood symptoms known as premenstrual dysphoric disorder (PMDD). This is a mood-related condition recognized by the *Diagnostic and Statistical Manual*, *5th edition* (*DSM-5*; see diagnostic criteria) and can have significant impact on a patient's quality of life, productivity and interpersonal relationships. The prevalence of PMDD ranges from 1.3% to 9%.[32,50]

Individuals experiencing PMS and PMDD symptoms miss significantly more work and school compared to those without PMS or PMDD. They also report significant impairment of their ability to participate in social activities, hobbies, and in their relationships with others, as well having a lower health-related quality of life and higher medical expenses.[32]

An exact PMS prevalence is difficult to ascertain, because symptoms and severity tend to fluctuate.

Etiology

While it is unclear why PMS occurs, there are theories. First, it is thought that patients with PMS have an underlying neurological vulnerability to the normal cyclic hormonal fluctuations that occur during the menstrual cycle. When ovulation is suppressed medically or surgically, symptoms usually improve. It is thought that abnormal serotonergic function plays a role with mood related symptoms and cravings as well as PMDD.[51]

Pathophysiology

According to some evidence PMS and PMDD symptoms are related to low levels of the centrally active progesterone metabolite allopregnanolone in the luteal phase and/or lower cortical γ-aminobutyric acid levels in the follicular phase.[51] A number of studies suggest a link between PMS and PMDD and low serotonin levels.[51] Although several cross-cultural studies suggest PMS physical symptoms are consistent across cultures, the negative affective symptoms are part of the negative "menstrual socialization" in western culture.[51]

Premenstrual Dysphoric Disorder Clinical Presentation

CLINICAL PRESENTATION: Premenstrual Dysphoric Disorder

A summary of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* criteria for PMDD is as follows[74]:

- Symptoms are temporally associated with the last week of the luteal phase and remit with the onset of menses.
- At least five of the following symptoms are present: affective lability, anger, or irritability often characterized by interpersonal conflicts, markedly depressed mood, anxiety, decreased interest in activities, fatigue, difficulty concentrating, changes in appetite, sleep disturbance, feelings of being overwhelmed, and physical symptoms, such as breast tenderness or bloating.
- One of the symptoms must be affective lability, irritability, markedly depressed mood, or anxiety.
- Symptoms interfere significantly with work and/or social relationships.
- Symptoms are not an exacerbation of another underlying psychiatric disorder.
- The criteria are confirmed prospectively by daily ratings over two menstrual cycles and must have occurred during most menstrual cycles in the past year.

Treatment

Desired Outcome

Treatment of PMS and PMDD attempts to relieve psychiatric and somatic symptoms through ovulation suppression, or through affecting neurotransmitter (eg, serotonin, norepinephrine, or dopamine) concentrations in the brain.[32] Therefore, PMS and PMDD interventions should alleviate the presenting symptoms and subsequently improve quality of life. Table 100-3 lists the various agents used in managing PMS and PMDD and their recommended dosing.

General Approach to Treatment

A treatment modality that is minimally invasive or without systemic effects is desired for initial therapy. Key to the successful choice of pharmacologic therapy for PMS and PMDD is having the patient chart their specific symptoms for at least two menstrual cycles to assist in ruling out premenstrual exacerbation of underlying psychiatric disorders.

Nonpharmacological Therapy

Some lifestyle changes for the management of mild-to-moderate premenstrual symptoms include minimizing intake of caffeine, refined sugar, and sodium and increasing exercise.[33] Although exercise appears to improve PMS symptoms, definitive, evidence-based recommendations cannot be made due to methodological limitations of these studies.[33] Vitamin and mineral supplements, such as vitamin B_6 (50-100 mg daily) and calcium carbonate (1,200 mg daily), may help to reduce the physical symptoms associated with PMS; however, clinical trial data is limited and/or mixed precluding a definitive conclusion regarding their use.[33] Cognitive behavioral therapy has also been studied showing moderate efficacy.[33] However, the frequency and duration therapy have not been defined. Nonetheless, acceptance-based cognitive behavior therapy and mindfulness-based exercises may be helpful in reducing symptoms.[32] A Cochrane review of herbal supplements for PMS, including angelica root, bitter orange, dragon's teeth, ginkgo, peppermint, saffron, turmeric, tangerine leaf, and vitex agnus-castus, among others, do not support their use.[52,53] Although acupuncture and acupressure appear to improve physical and psychological symptoms of PMS, evidence was from limited sample sizes and of low quality.[54]

Pharmacologic Therapy

Investigations have focused on the selective serotonin reuptake inhibitors (SSRIs) for this disorder.[34] Studies have revealed positive results relative to most symptoms associated with PMDD. Other agents that have been studied and are alternatives include the selective serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine, as well as CHCs and GnRH agonists.

Among SSRIs, data support the use of citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline for the treatment of severe mood related symptoms of PMS and PMDD.[32,33] Research evaluating the dosing of these agents continuously or only during the luteal phase (ie, days 14-28 of the menstrual cycle) has illustrated similar efficacy between the two regimens, such that one cannot be recommended over another although more studies directly comparing continuous versus luteal phase administration are needed.[32,33] Treatment decisions will often be based on patient preference as some prefer continuous dosing so they do not have to track their cycle as closely, whereas some prefer just taking the medication during the luteal phase to minimize medication exposure. Interestingly, when used in PMDD, antidepressants tend to be very effective and have a faster onset than what is typically seen in the treatment of major depression. Most medication adverse effects also appear to be similar between continuous and luteal dosing, except decreased libido which occurs at a higher rate with continuous dosing.[33] In addition, abrupt cessation of SSRI at the end of the menstrual cycle is not associated with discontinuation symptoms.[35] All SSRI doses appear to be effective for psychiatric symptoms, and should be titrated to individual patients' symptom improvement and tolerability.[32] The safety of SSRIs use during early pregnancy has been an active area of investigation. In a large-scale analysis, reassuring evidence was provided for some SSRIs, but birth defects (including anencephaly, atrial septal defects, right ventricular outflow tract obstruction, and gastroschisis) can be 2 to 3.5 times more frequent with paroxetine or fluoxetine use in early pregnancy.[55]

The SNRI, venlafaxine, has been studied for PMDD and, similar to the SSRIs, found to result in a 50% or greater improvement in symptoms in 60% of treated patients compared with only 35% in the control group.[33] The norepinephrine and dopamine reuptake inhibitor, bupropion, has not been proven effective for PMS or PMDD.[32]

It is important that concomitant pharmacotherapy be evaluated closely for pharmacokinetic interactions when an SSRI or venlafaxine is prescribed, given the interface of these medications with cytochrome P450 isoenzyme systems. Additional information regarding antidepressant dosing, adverse medication effects, pharmacokinetics, and medication interactions can be found in Chapter 88, "Depressive Disorders."

The use of a monophasic oral CHC containing 20 mcg of ethinyl estradiol and 3 mg of drospirenone, a progesterone with antiandrogenic effects, improves premenstrual symptoms in persons with PMDD, and is FDA approved for this indication.[33] The continuous cycle CHC regimen delivering 90 mcg of levonorgestrel and 20 mcg of ethinyl estradiol daily has also been studied in controlled trials resulting in a 30% to 59% improvement in PMDD symptoms.[36] For PMS symptoms, in a large-scale study, both triphasic and monophasic CHCs led to reduction in physical symptoms but not mood symptoms.[33] Superiority of one CHC relative to another has not been established.

If treatment with the above options is unsuccessful, hormonal treatment with a GnRH agonist, such as leuprolide, can be considered.[33] Leuprolide improves premenstrual emotional symptoms as well as some physical symptoms, such as bloating and breast tenderness. However, its cost, the need for intramuscular administration, and its hypoestrogenism effects (eg, vaginal dryness, hot flashes, and bone demineralization) severely limit its use.[35] Table 100-4 lists the significant pharmacologic properties for agents used to treat PMDD that require monitoring.

Evaluation of Therapeutic Outcomes

Table 100-4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in PMDD management.

DYSMENORRHEA

Epidemiology

Dysmenorrhea is one of the most commonly encountered gynecologic complaints and is defined as crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the setting of normal pelvic anatomy and physiology, while secondary dysmenorrhea is associated with underlying pelvic pathology.[56,57] Dysmenorrhea prevalence rates vary but range from 16% to 90%, and its presence may be associated with significant interference in work and school attendance.[57] In addition, significant reductions in quality of life and lower overall life satisfaction and contentment ratings have been observed in patients with dysmenorrhea compared to controls.[56] Risk factors include menarche before the age of 12 years, current age less than 30 years, heavy menses, nulliparity, low body mass index, and a history of sexual abuse.[57]

Etiology

For most patients, dysmenorrhea is accompanied by normal ovulatory cycles and normal pelvic anatomy. This is referred to as primary, or functional, dysmenorrhea.[58] Primary dysmenorrhea typically occurs within 6 to 12 months of menarche, when adolescents attain ovulatory cycles.[21] However, in approximately 10% of the adolescents and young adults presenting with painful menses, an underlying anatomic or physiologic cause exists.[57] Comparatively, secondary dysmenorrhea associated with pelvic pathology should be suspected in patients over 30 years of age without a history of dysmenorrhea.[50]

Pathophysiology

The most significant mechanism for primary dysmenorrhea is the release of prostaglandins and leukotrienes into the menstrual fluid, initiating an inflammatory response and vasopressin-mediated vasoconstriction.[19,23] The most common cause of secondary dysmenorrhea is endometriosis. Other causes include current or history of pelvic inflammatory disease, uterine fibroids, Müllerian anomalies, obstructive reproductive tract abnormalities, and adenomyosis leiomyomata.[39,57] Pregnancy and miscarriage must be considered in new-onset dysmenorrhea.

Dysmenorrhea Clinical Presentation

CLINICAL PRESENTATION: Dysmenorrhea

General

- Patients may or may not be in acute distress, depending on the level of menstrual pain experienced

Symptoms

- Patients complain of crampy pelvic pain beginning shortly before or at the onset of menses. Symptoms typically last from 8 to 72 hours.
- Associated symptoms may include low back pain, headache, diarrhea, fatigue, and/or nausea and vomiting.

Laboratory Tests

- Pelvic examination should be performed to screen for sexually transmitted diseases and/or pelvic inflammatory disease as a cause of the pain in sexually active females.
- Gonorrhea, Chlamydia cultures or polymerase chain reaction, wet mount.

Other Diagnostic Tests

- Transvaginal/pelvic ultrasound can be used to identify potential anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

Treatment

Desired Outcomes

Initial treatment choice is influenced by whether or not the patient desires pregnancy. Medical management of dysmenorrhea should relieve the pelvic pain, result in reducing lost school and work days, and contribute to an improved quality of life. Table 100-3 identifies the agents used to manage dysmenorrhea and their recommended doses. Figure 100-4 shows a treatment algorithm for dysmenorrhea management. Note that if symptoms persist for 3 to 6 months further work-up for secondary dysmenorrhea is warranted.

General Approach to Treatment

A variety of effective treatment options for dysmenorrhea are available, including nonhormonal and hormonal pharmacologic options and noninvasive nonpharmacologic options. Treatment choice is influenced by the desire for contraception, the patient's level of sexual activity, potential for adverse effects, and cost. For patients suffering from secondary dysmenorrhea due to endometriosis, treatment is directed toward management of symptoms, prevention of disease progression, and protection of future fertility, if desired. Treatment of endometriosis is covered in Chapter 101.

Nonpharmacologic Therapy

Several nonpharmacologic interventions are used for managing dysmenorrhea. Among these, topical heat therapy, exercise, acupuncture, and a low-fat vegetarian diet have been shown to reduce dysmenorrhea intensity.[57,59,60] Dietary changes may shorten dysmenorrhea duration. Topical heat application via an abdominal patch is as effective as 400 mg of ibuprofen dosed three times daily. [41,61] Because topical heat, exercise, and dietary changes do not impart systemic effects, they are associated with little to no risk compared to the pharmacologic options. Although a variety of dietary supplements, including fenugreek, fish oil, vitamin B1, ginger, valerian, and zinc sulfate, have been evaluated for dysmenorrhea, a Cochrane analysis concluded that evidence supporting their use is of low or very low quality due to limited sample sizes and methodological concerns.[62] Similarly, although there is some evidence supporting the use of acupuncture and acupressure, a Cochrane analysis also concluded that the quality evidence was low or very low.[60]

Pharmacologic Therapy

Given the role of prostaglandins in dysmenorrhea pathophysiology, NSAIDs are the initial treatment of choice. These agents do not differ in efficacy with the most commonly used agents being naproxen and ibuprofen.

All NSAIDs have a propensity for causing GI distress and ulceration; their administration with food or milk minimizes these effects. In patients who have a history of NSAID-induced gastric effects, the use of celecoxib, a cyclo-oxygenase-2 (COX-2) inhibitor, is an alternative.[23] Increasing fluid intake may also help reduce renal adverse effects.[21] Choice of one agent over another may be based on cost, convenience, and patient preference.[21] All NSAIDs should be dosed on an individual basis and are most effective if started 1 to 2 days prior to the onset of menses and continued through the first 2 to 3 days of menstrual bleeding.[21] According to some research NSAID therapy should begin at the onset of menses or perhaps even the day before and continued around the clock instead of waiting until symptom onset; however, the data substantiating this are weak.[63] Acetaminophen is inferior to NSAID use in the treatment of this disorder.[23] Opioid should be avoided for dysmenorrhea pain management as adolescents can develop dependence in as few as 7 days, leading to physical withdrawal symptoms.[21] If an NSAID or celecoxib use is contraindicated or not desired, hormonal agents should be considered.

Overall, the CHCs improve dysmenorrhea by inhibiting endometrial tissue proliferation which reduces endometrial-derived prostaglandins and leukotrienes that cause the pelvic pain.[19,21] Significant improvements in mild, moderate, and severe dysmenorrhea have been noted with CHCs. Although one study suggested that a CHC containing a potent progestin (eg, levonorgestrel) may be more beneficial, other studies using CHCs with other progestins suggest that pain reduction is not limited to levonorgestrel-containing regimens.[22] Compared with cyclic regimens, continuous CHC regimens may result in more rapid pain reduction.[21] However, both cyclic and continuous regimens have been used successfully.[21]

Long-acting progesterones, such as depot MPA and the LNG-IUS, can be considered for dysmenorrhea treatment. Their efficacy is secondary to their ability to render most patients amenorrheic within 6 to 12 months of use.[19,22] Because the pelvic pain of dysmenorrhea is related to the prostaglandins released during menses, in the setting of amenorrhea the underlying cause of dysmenorrhea is removed.

Several factors influence the choice of first-line treatment for dysmenorrhea. If contraception is desired, then a hormonal option may be considered taking into account cost, adherence issues, and adverse effects. If contraception is not desired, then NSAID use would be desirable from both cost and convenience standpoints. If NSAIDs are not tolerated, celecoxib could be recommended. In patients for whom hormonal contraception, NSAIDs, or celecoxib are not an option, topical heat should be considered.

Adolescents

According to the American College of Obstetricians and Gynecologists, adolescents are particularly at risk of receiving delayed medical care for symptoms of dysmenorrhea.[39] Because NSAIDs impact prostaglandin production specifically, they are recommended as the initial treatment choice for adolescents with primary dysmenorrhea.[39] Adolescent patients are more likely to engage in self-directed treatment use of NSAIDs and, therefore, are at higher risk of sub-therapeutic treatment. Early diagnosis, treatment, and education is essential in this population.[39] In adolescent patients desiring contraception, or in whom NSAIDs do not provide adequate relief, hormonal contraceptives can be used alone, or in combination with NSAIDs.[21] Prolonged use of depot MPA may lead to significant loss of bone mineral density (BMD) loss which may not be completely reversible after depot MPA discontinuation.[22] Adolescence is a critical period for BMD accrual. Hence, depot MPA may not be the first choice in this population.[22] Table 100-4 identifies the significant pharmacologic properties for agents used to treat dysmenorrhea that require monitoring.

Evaluation of Therapeutic Outcomes

Table 100-4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of dysmenorrhea.

ABNORMAL UTERINE BLEEDING WITH OVULATORY DYSFUNCTION

Epidemiology

⑦ Abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O) is caused by oligo- or anovulation, leading to irregular, heavy menstrual bleeding due to chronic unopposed estrogen on the endometrium.[18] While it does encompass bleeding patterns such as HMB and amenorrhea, this section will focus specifically on AUB-O as it relates to oligo-anovulation.

The estimated annual prevalence of menstrual irregularities is 53 per 1,000 females.[63] In reproductive-age females, polycystic ovary syndrome (PCOS) is one of the most common causes of AUB-O,[18] with a prevalence range of 8% to 13%.[64] In perimenopausal individuals, bleeding changes are due to normal menopausal transition, with the average age of menopause being 51 years in developed countries. In North America, the mean duration of menopausal transition is 4 years, and during this time period menstrual irregularity is commonly observed.[18]

Etiology

When considering the etiology of AUB-O, the patient's age must be taken into account. As previously discussed, all patients presenting with abnormal bleeding should be evaluated for pregnancy. In adolescents though, anovulation is the most common cause of AUB-O.[18] During the first 12 to 18 months after menarche, immaturity of the HPO axis is frequently the cause of AUB-O.[18] By the third year after the onset of menstruation, 60% to 80% of cycles are regular.[18] If regular menstrual cycles have not been established within 5 years of menarche, further evaluation for the cause, such as PCOS, should be considered.[31] When irregular menses is associated with significant bleeding, an inherited bleeding disorder should be considered as a cause, especially in adolescence.[18] Individuals experiencing AUB-O in their reproductive years should be evaluated for pathologic causes, including PCOS, thyroid dysfunction, hyperprolactinemia, primary pituitary disease, premature ovarian failure, hypothalamic dysfunction, disordered eating, adrenal disease, and androgen-producing tumors.[18] Individuals in their perimenopausal years may experience "physiologic" anovulatory cycles because of intermittently declining estrogen levels. Regardless of age, evaluation for endometrial hyperplasia and/or endometrial cancer should be considered when a patient experiences excessive bleeding with irregular menses.[18] When considering the etiology of AUB-O, more than one condition may coexist (eg, PCOS and hypothyroidism), each contributing to the constellation of symptoms.

Pathophysiology

Normal menstrual cycles occur through a complex interaction of the hypothalamus, pituitary gland, ovaries, and endometrium (see Fig. 100-1). In an ovulatory cycle, the ovary produces a mature, estrogen-secreting follicle in response to FSH release from the pituitary. The endometrium proliferates under the influence of this estrogen production. At a critical level of estrogen concentration, the pituitary responds by producing an "LH surge," which creates a cascade of ovarian events, culminating in ovulation. Upon oocyte release, the follicle becomes a progesterone-producing corpus luteum. The endometrium "organizes" into secretory endometrium in the presence of adequate progesterone, preparing itself for a possible pregnancy. If conception and implantation do not occur, corpus luteum involution causes a decline in estrogen and progesterone leading to predictable, organized menstrual flow as the endometrium sloughs.

If ovulation does not occur, progesterone is not produced, and the endometrium will continue to proliferate in an “unorganized” fashion under the influence of continued estrogen production. Eventually, the endometrium will become so thick that it can no longer be supported by continued estrogen production. This results in unorganized, sporadic sloughing of the endometrium, characteristic of the unpredictable and heavy bleeding associated with AUB-O.

Overall, AUB-O has various etiologies, which will require a careful history and examination along with laboratory assessments to elucidate. For example, in adolescence, HPO axis immaturity contributes to the absence of the LH surge required for ovulation. In patients with anorexia, the hypothalamus loses much of its pulsatile GnRH release, leading to low levels of FSH and LH, and in certain cases enough for estrogen production but not enough to induce ovulation. Oocyte decline and abnormal follicular development contribute to anovulatory cycles common among individuals in the perimenopause transition.[18]

⑧ In females of reproductive-age, PCOS is one of the most common causes of AUB-O.[18] Generally, PCOS can present as AUB-O, and symptoms include amenorrhea, oligomenorrhea, intermenstrual bleeding, and HMB. Although its exact definition continues to evolve, it is a disorder of androgen excess accompanied by ovulatory dysfunction and/or polycystic ovarian morphology.[65,66] Insulin resistance is often present, and PCOS is a risk factor for the metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and possibly cardiovascular disease.[31] Besides PCOS, common causes of AUB-O in reproductive-age females include hyperprolactinemia, hypothalamic amenorrhea, also known as hypogonadotropic hypogonadism, primary ovarian insufficiency, and thyroid dysfunction.[18]

The criteria for diagnosing PCOS in adolescents are controversial as the pathologic features used for the diagnosis in adults, specifically acne and irregular menses, may be normal pubertal occurrences. Adolescent hyperandrogenism (as opposed to adult hyperandrogenism) may be a natural consequence of the lack of synchronicity within the HPO axis during prolonged anovulatory cycles that are typical during puberty. Additionally, there is a high background prevalence of polycystic ovarian morphology in this population.[67] Menstrual irregularity for over 2 years and accurate assessment of hyperandrogenic as well as metabolic features, in addition to reduced reliance on ultrasound diagnosis of polycystic ovarian morphology, may be suitable strategies for PCOS diagnosis in the adolescent population.[67] More research is needed to definitively identify the appropriate diagnosis of PCOS among adolescents so that appropriate treatment(s) can be recommended.

Abnormal Uterine Bleeding with Ovulatory Dysfunction Clinical Presentation

CLINICAL PRESENTATION: Abnormal Uterine Bleeding with Ovulatory Dysfunction

General

- Patients typically will not be in acute distress.

Symptoms

- Irregular, heavy, or prolonged uterine bleeding.
- Perimenopausal symptoms (eg, hot flashes, night sweats, and vaginal dryness) in ovarian insufficiency or menopausal transition.

Signs

- Acne, hirsutism, and obesity in PCOS

Laboratory Tests

- Pregnancy testing
- If PCOS is suspected, consider free or total testosterone, fasting glucose, fasting lipid panel
- If perimenopause is suspected, measure FSH
- Thyroid-stimulating hormone

Other Diagnostic Tests

- Endometrial biopsy for patients with risk factors for endometrial hyperplasia or malignancy
- Pelvic ultrasound to evaluate for polycystic ovaries

Treatment

Desired Outcomes

The optimal therapy for AUB-O depends upon the underlying cause(s) and the treatment options for AUB-O are wide and varied. When applicable, control of excessive bleeding in the short term is paramount. Longer-term goals of therapy include restoring the natural cycle of orderly endometrial growth and shedding, preventing endometrial hyperplasia,[18] addressing fertility concerns, decreasing the risk of osteopenia in cases of ovarian insufficiency, and improving the overall quality of life. Table 100-3 identifies the agents used to manage AUB-O and their recommended doses. Medical treatment, as opposed to surgical management, to resolve AUB-O should be initiated, as AUB-O is primarily an endocrinologic abnormality.[18]

Nonpharmacologic Therapy

Nonpharmacologic treatment options for AUB-O depend on the underlying cause. In a female of reproductive age with PCOS, weight loss of 5% to 10% may result in improved menstrual regularity and ovulatory function, reduced hirsutism, increased insulin sensitivity, and improved response to fertility treatments.[30] Further, sustained weight loss has resulted in a return to ovulatory cycles in those without PCOS who experienced anovulatory cycles.[18] In patients with AUB-O who have completed childbearing or who have not responded to medical management, endometrial ablation or resection and hysterectomy are surgical options. In the short term, ablation results in less morbidity and shorter recovery periods compared to other surgical interventions. However, patients should be counseled about the risks regarding the ability to detect and diagnose endometrial cancer in the future.[18] Importantly, procedure choice involves shared decision making with the patient.

Pharmacologic Therapy

Hormonal contraceptives prevent recurrent AUB-O by providing a progestin and suppressing ovarian hormones. The CHCs are also useful for cycle regulation, leading to predictable menstrual cycles. In individuals with contraindication(s) to estrogen or in whom the adverse medication effects are unacceptable, progesterone-only products are an option. They should be strongly considered for patients experiencing HMB associated with anovulatory cycles.[18] Depot and intermittent oral MPA provide endometrial protection through endometrial suppression.[4] Another progesterone option is placement of the LNG-IUS,[18] particularly if pregnancy is not desired. Studied specifically in females over 30 years of age, use of the LNG-IUS resulted in a greater than 95% reduction in menstrual blood loss by 2 years.[68] Patient satisfaction rates were greater than 80%, with 74% agreeing to recommend it to others.[68]

⑨ For individuals with PCOS who have high androgen levels and its related signs (eg, hirsutism), CHCs also increase sex hormone-binding globulin (SHBG) which binds androgens and reduces their circulating free concentrations. The 2018 international PCOS guideline recommends that CHCs alone should be recommended in adults and adolescents with PCOS for management of irregular menstrual cycles and clinical hyperandrogenism.[30] For patients with PCOS, CHCs containing less than or equal to 35 mcg of ethinyl estradiol and a progesterone that exhibits minimal androgenic effects (eg, norgestimate and desogestrel) or with antiandrogenic effects (eg, drospirenone) may be desirable.

The 2018 international PCOS guidelines also recommend that metformin should be considered in adults and adolescents with PCOS for management of metabolic features when lifestyle changes do not achieve desired goals.[30] Although metformin improves insulin sensitivity, and can reduce circulating androgen concentrations and improve ovulation rates,[31,69] CHCs are more effective in cycle regulation and decreasing androgens. The 2018 international PCOS guidelines recommend that metformin can be used in combination with CHCs for treatment of hyperandrogenic-related alopecia or hirsutism if at least 6 months of CHCs and cosmetic therapy do not adequately improve symptoms.[30] While not typically an issue among the relatively young population of patients treated with metformin for PCOS, one must be cognizant of the risk of lactic acidosis in metformin users with renal impairment. As such, this medication should be avoided in individuals with serum creatinine greater than 1.4 mg/dL (124 μmol/L). In addition, metformin may lead to spontaneous ovulation, and birth control should be advised in patients with PCOS not desiring pregnancy.[30]

Hormonal contraceptives containing antiandrogenic progesterones are very effective for managing the acne and hirsutism that accompany PCOS as they suppress ovarian androgen production and increase SHBG, thus reducing free testosterone concentrations. Controversy regarding their use in PCOS exists secondary to their potential adverse effects on insulin resistance and glucose tolerance.[70] An increase in high-sensitivity C-reactive protein and an increase in homocysteine levels, both indicators of cardiovascular risk, have been observed with the use of CHCs.[58] Another trial found a reduction in brachial artery flow-mediated dilatation and an increase in carotid intima-media thickness, both indicators of endothelial dysfunction, following therapy with oral CHCs containing ethinyl estradiol and cyproterone acetate in patients with PCOS.[71] Additional, longer-term clinical trials will clarify whether the benefits of these agents outweigh the risks. It has been suggested that cardiovascular risk calculators be employed as an adjunct to guidelines suggesting the use of oral CHCs in this patient population.[72]

If the treatment goal is fertility, letrozole should be considered first-line treatment for ovulation induction in individuals with PCOS with anovulatory infertility and no other infertility factors.[30] Letrozole has been found to lead to significantly more ovulatory cycles, pregnancies, and live births compared to clomiphene in patients with PCOS.[73] It is dosed at 2.5 mg daily for 5 days beginning on cycle day 3 after induced withdrawal bleeding with a progesterone such as MPA 10 mg daily orally for 10 days. If ovulation does not occur, doses can be increased in subsequent cycles to a maximum of 7.5 mg daily in up to 5 cycles.[73] As an alternative ovulation induction agent, clomiphene citrate is administered in a similar manner, initiated at 50 mg daily, with dose increase in subsequent cycles to a maximum of 150 mg daily.[73]

Overall, the treatment(s) of choice depends on accurate etiologic diagnosis as well as identification of the desired treatment outcome(s). Hormonal contraceptives are the first-choice treatment in individuals with AUB-O who do not desire pregnancy.[18] In those with PCOS, CHCs are first-line pharmacologic agents for cycle control and minimizing the androgenic signs and symptoms of PCOS, while metformin is primarily used for metabolic improvement when lifestyle interventions do not yield adequate improvements.[30] Letrozole is used for ovulation induction in PCOS.[30] Table 100-4 lists the important pharmacologic properties of agents used to treat AUB-O that require monitoring.

Perimenopause

Anovulatory cycles are fairly common in the perimenarchal reproductive years. Ovulation typically is established 1 year or more following menarche. If excessive bleeding occurs, the patient should be evaluated for bleeding disorders, as HMB since menarche may indicate an undetected coagulopathy.[25] If identified, the specific bleeding disorders should be treated. Acute severe bleeding can be managed with intravenous conjugated equine estrogen, high-dose CHCs, or high-dose oral progestins.[44]

Evaluation of Therapeutic Outcomes

Table 100-4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used to manage AUB-O.

FIGURE 100-4

Treatment algorithm for dysmenorrhea. (LNG-IUS, levonorgestrel-releasing intrauterine system; MPA, medroxyprogesterone acetate; NSAIDs, nonsteroidal anti-inflammatory drugs; CHC, combined hormonal contraceptive)

CONCLUSION

Problems related to the menstrual cycle are very common in females of reproductive age. The most frequently encountered menstruation-related difficulties include amenorrhea; heavy menstrual bleeding (HMB); abnormal uterine bleeding associated with ovulatory dysfunction (AUB-O), including polycystic ovary syndrome (PCOS); dysmenorrhea; and premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD). The diagnosis of various menstruation-related disorders begins with a thorough history of the patient’s menstrual patterns, co-occurring symptoms. Problems related to the menstrual cycle negatively affect quality of life, reproductive potential, and may have long-term detrimental health effects.

ABBREVIATIONS

ACOG	American College of Obstetricians and Gynecologists
AUB-O	abnormal uterine bleeding with ovulatory dysfunction
CHC	combined hormonal contraception
COX-2	cyclo-oxygenase-2
FHA	functional hypothalamic amenorrhea
FSH	follicle-stimulating hormone
GnRH	gonadotropin-releasing hormone
HC	hormonal contraceptive
HMB	heavy menstrual bleeding
HPA	hypothalamic–pituitary–adrenal
HPO	hypothalamic–pituitary–ovarian
IUSs	Intrauterine systems
hCG	human chorionic gonadotropin
LH	luteinizing hormone
LNG-IUS	levonorgestrel-releasing intrauterine system
MPA	medroxyprogesterone acetate
NSAID	nonsteroidal anti-inflammatory drug
PCOS	polycystic ovary syndrome
PMDD	premenstrual dysphoric disorder
PMS	premenstrual syndrome
SHBG	sex hormone-binding globulin
SNRI	serotonin–norepinephrine reuptake inhibitor
SSRI	selective serotonin reuptake inhibitor

SELF-ASSESSMENT QUESTIONS

1. JT is a 17-year-old who complains of amenorrhea for 6 months. She experienced menarche at the age of 14 years and a pregnancy test is performed and found to be negative. This patient is a distance runner who describes her appetite as "healthy." Her BMI is 21 kg/m^2. What is the next step in evaluating this complaint?

A. Check her serum prolactin concentration

B. Check her thyroid-stimulating hormone (TSH) concentration

C. Quantify her level of exercise

D. Evaluate whether she may have anorexia

2. Regardless of the etiology of amenorrhea, which of the following lifestyle interventions is most appropriate?

A. Increase the dietary intake of folate and vitamin E

B. Increase the dietary intake of calcium and vitamin D

C. Decrease the intake of alcohol

D. Decrease the level of exercise

3. KS is a 36-year-old patient who has not had a period for 8 months. She is not pregnant and have a serum prolactin concentration twice the upper limit of normal. There are no symptoms of polycystic ovary syndrome (PCOS). Which of the following is most appropriate for KS now?

A. An oral contraceptive containing 30 μg ethinyl estradiol plus levonorgestrel

B. Bromocriptine 2.5 mg by mouth three times daily

C. Medroxyprogesterone acetate (MPA) 10 mg by mouth for 10 days

D. Metformin 1,000 mg by mouth twice daily

4. BJ is a 14-year-old female who started having menses 7 months ago. Her menses is irregular, with cycle length ranging from 32 days to 75 days. What is the best cause of action now?

A. Evaluate BJ for hypothyroidism

B. Evaluate BJ for polycystic ovary syndrome (PCOS)

C. Evaluate BJ for bleeding disorders

D. Educate BJ that her menstrual irregularity is expected

5. Which of the following statements is true regarding the levonorgestrel-releasing intrauterine system (LNG-IUS) in an individual with HMB?

A. It should never be used in nulliparous females.

B. It reduces menstrual flow by a maximum of 25%.

C. It is a therapeutic option for any individual at low risk for sexually transmitted infections.

D. Its use increases the need for hysterectomy.

6. In patients with PCOS whose primary concern is menstrual irregularity, who is not attempting pregnancy, which of the following is the initial therapeutic option after a trial of applicable lifestyle intervention?

A. Metformin

B. A combination oral contraceptive containing ethinyl estradiol and drospirenone

C. LNG-IUS

D. Letrozole

7. BB is a 32-year-old patient who initially presented with complaints of irregular menses and excess hair growth around the jawline. She was diagnosed with PCOS and was started on an oral contraceptive and lifestyle modification. Today at her 6-month follow-up appointment, her BMI is 35 kg/m^2 with a waist circumference of 40 in. (102 cm). A 2-hour oral glucose tolerance test suggests impaired glucose tolerance. Which of the following is the most appropriate option for BBnow?

A. Continue her oral contraceptive

B. Discontinue her oral contraceptive and initiate a LNG-IUS

C. Discontinue her oral contraceptive and initiate letrozole

D. Add metformin

8. Hyperkalemia is most likely to result from which of the following products used in the management of PCOS?

A. A combination oral contraceptive containing ethinyl estradiol and drospirenone

B. A combination oral contraceptive containing ethinyl estradiol and levonorgestrel

C. Metformin 850 mg by mouth twice daily

D. Injectable medroxyprogesterone acetate (MPA), 150 mg dosed every 12 weeks

9. JK has PCOS that was previously treated with a combined oral contraceptive. She discontinued oral contraceptive use 14 months ago to attempt pregnancy. During these 14 months, there have been two menstrual periods, both with heavy bleeding. A pregnancy test today is negative. Which of the following is the most appropriate treatment?

A. Clomiphene 50 mg daily orally for 5 days

B. MPA 10 mg daily orally for 10 days

C. MPA 10 mg daily orally for 10 days, followed by letrozole 2.5 mg orally daily for 5 days beginning on cycle day 3 after induced withdrawal bleeding

D. MPA 10 mg daily orally for 10 days, followed by metformin 550 mg orally daily and titrated to 2,000 mg total daily dose

10. Excessive anovulatory bleeding in the adolescent population should result in an evaluation for:

A. Hypoprothrombinemia

B. Hyperandrogenism

C. Hypoestrogenism

D. Hypothyroidism

11. Which of the following agents is most appropriate for the management of dysmenorrhea in an adolescent who is not sexually active?

A. Depot MPA 150 mg intramuscularly every 12 weeks

B. Ibuprofen 800 mg by mouth three times daily during menses

C. LNG-IUS releasing 20-µg levonorgestrel daily

D. Oral contraceptive with 35-µg ethinyl estradiol plus norgestimate daily

12. The most cost-effective treatment for heavy menstrual bleeding is:

A. A combination oral contraceptive

B. LNG-IUS

C. Oral MPA

D. Depot MPA

13. Which of the following nonpharmacologic options is effective for the treatment of dysmenorrhea?

A. High protein diet

B. Topical ice packs

C. Reduced exercise

D. Topical heat

14. Dysmenorrhea is experienced by as many as _______% of females of childbearing age.

A. 20

B. 40

C. 70

D. 90

15. CO is a 30-year-old patient diagnosed with PMDD after charting symptoms for two cycles and attempting nonpharmacologic interventions for her symptoms without much relief. This patient is married and does not wish to use any form of birth control. Which of the following agents would be most appropriate for managing CO's PMDD?

A. Continuous treatment with paroxetine

B. Luteal phase treatment with fluoxetine

C. Luteal phase treatment with sertraline

D. 90-µg levonorgestrel and 20-µg ethinyl estradiol dosed continuously for 12 months

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Given that JT is a distance runner, and reported a healthy appetite, the most likely cause of amenorrhea is excess physical activity. Although hyperprolactinemia and hypothyroidism could be a possibility, they are not the most probable cause given the patient's history (see subsection "Pathophysiology" under section "Amenorrhea").

2. **D.** Among the choices presented, only physical exercise has been associated with amenorrhea (see subsections "Nonpharmacologic Therapy" and "Pharmacologic Therapy" under section "Amenorrhea").

3. **B.** The initial treatment of hyperprolactinemia is bromocriptine. Although an oral contraceptive and cyclical medroxyprogesterone acetate (MPA) can produce predictable menses, they do not address high prolactin levels (see subsection "Pharmacologic Therapy" under section "Amenorrhea"; also Table 100-3 for amenorrhea related to hyperprolactinemia).

4. **D.** During the first 12 to 18 months after menarche, immaturity of the hypothalamic–pituitary–ovarian axis is frequently the cause of ovulatory abnormal uterine bleeding. By the third year after the onset of menstruation, 60% to 80% of cycles are regular. If regular menstrual cycles have not been established within 5 years of menarche, further evaluation for the cause, such as polycystic ovary syndrome (PCOS), should be considered (see subsection "Etiology" under section "Abnormal Uterine Bleeding with Ovulatory Dysfunction").

5. **C.** Although historically it was believed that intrauterine devices (IUS) use should be avoided in nulliparous females, guidelines from the American College of Obstetricians and Gynecologists indicate that both nulliparous and multiparous individuals at low risk of sexually transmitted illnesses are good candidates for IUS use. IUSs are not associated with an increased risk of uterine pathology necessitating a hysterectomy (see Special Populations under subsection "Treatment" under section "Heavy Menstrual Bleeding").

6. **B.** The 2018 international PCOS guideline recommends that combined hormonal contraceptives (CHCs) alone should be recommended in adults and adolescents with PCOS for management of irregular menstrual cycles and clinical hyperandrogenism. For those with PCOS, CHCs containing less than or equal to 35 mcg of ethinyl estradiol and a progesterone that exhibits minimal androgenic effects (eg, norgestimate and desogestrel) or with antiandrogenic effects (eg, drospirenone) is desirable (see subsection "Pharmacologic Therapy" under section "Abnormal Uterine Bleeding with Ovulatory Dysfunction").

7. **D.** The 2018 international PCOS guidelines recommend that metformin should be considered in adults and adolescents with PCOS for management of metabolic features when lifestyle changes do not achieve desired goals. Given the patient’s impaired glucose tolerance, the addition of metformin is the most appropriate choice (see subsection "Pharmacologic Therapy" under section "Abnormal Uterine Bleeding with Ovulatory Dysfunction").

8. **A.** Of the options listed, only drospirenone carries a risk of hyperkalemia (see Table 100-4, drospirenone-containing CHC).

9. **D.** The 2018 international PCOS guidelines recommend that if the treatment goal is fertility, in individuals with PCOS with anovulatory infertility and no other infertility factors, letrozole should be considered first-line treatment for ovulation induction. Letrozole should be started at 2.5 mg orally daily for 5 days beginning on cycle day 3 after induced withdrawal bleeding with a progesterone such as MPA. Although clomiphene also induces ovulation and improves pregnancy and live birth rates compared to metformin, it is less efficacious than letrozole in a double-blind controlled clinical trial (see subsection "Pharmacologic Therapy" under section "Abnormal Uterine Bleeding with Ovulatory Dysfunction").

10. **A.** Anovulatory cycles are common in the perimenarchal reproductive years. Recommendations indicate that heavy menstrual bleeding following menarche can be highly indicative of an undetected coagulopathy as opposed to a menstrual abnormality related to hormonal irregularities (see subsection "Perimenopause" under section "Abnormal Uterine Bleeding with Ovulatory Dysfunction").

11. **B.** Treatment choice for dysmenorrhea is influenced by the patient’s level of sexual activity and/or their desire for contraception. In this case, as contraception is neither desired nor needed, the nonhormonal option of a nonsteroidal anti-inflammatory agent, ibuprofen, is desirable (see subsection "Desired outcomes" under section "Dysmenorrhea" and Table 100-3).

12. **B.** Among all hormonal agents available to manage heavy menstrual bleeding, all cost-effectiveness data support the LNG-IUS above all other options (see subsection "Pharmacologic Therapy" under section "Heavy Menstrual Bleeding").

13. **D.** The nonpharmacologic options shown to be effective in managing dysmenorrhea include low-fat vegetarian diet (NOT high protein), exercise (NOT reduced exercise), acupuncture, and topical heat. Topical ice packs have NOT been shown effective in managing dysmenorrhea (see subsection "Nonpharmacologic Therapy" under section "Dysmenorrhea").

14. **D.** The answer is 90% and the intent of asking this question is to raise awareness to the extreme prevalence of this disorder that so negatively impacts the quality of life of so many individuals (see subsection "Epidemiology" under section "Dysmenorrhea").

15. **C.** The SSRIs are considered the first-line treatments for PMDD. Evidence comparing luteal phase versus continuous dosing shows equal efficacy between the two dosing regimens. From a medication adverse effect standpoint, the luteal phase dosing is associated with LESS of a negative impact on libido when compared to continuous dosing. Birth defects have been noted to occur 2 to 3.5 times more frequently with paroxetine and fluoxetine. Further, this patient does NOT desire the use of any form of contraception (see subsection "Pharmacologic Therapy" under section "Premenstrual Syndrome and Premenstrual Dysphoric Disorder").

Chapter 101: Endometriosis

Kathleen Vest; Sarah E. Lynch

KEY CONCEPTS

KEY CONCEPTS

1 Endometriosis is a chronic condition in reproductive age females that can cause chronic pelvic pain and infertility.

2 Endometriosis is characterized by endometrial tissue outside the uterus, but the exact pathophysiology and biological mechanisms are multifactorial and still remain unclear.

3 Endometriosis should be suspected in any biological female of reproductive age presenting with recurring pelvic pain or otherwise unexplained infertility. Failure of first-line treatment options like nonsteroidal anti-inflammatory drugs (NSAIDs) or combined hormonal contraceptives (CHCs) to relieve dysmenorrhea is highly suspect of endometriosis.

4 Definitive diagnosis of endometriosis requires direct surgical visualization; however, it is acceptable to empirically treat these symptoms without a definitive diagnosis.

5 Treatment strategies are based on patient symptoms and preferences with regards to desire for pregnancy.

6 Pharmacologic and surgical options are indicated to treat endometriosis-associated pain. Surgery/reproductive technology is the only treatment option for endometriosis-related infertility.

7 Treatment options are not curative of endometriosis and only provide symptom management.

8 First-line pharmacologic options include NSAIDs, CHCs, and progestins. Other options include gonadotropin-releasing hormone (GnRH) agonists, GnRH antagonists, danazol, and aromatase inhibitors.

9 Add-back therapy can be utilized with certain agents to minimize hypoestrogenic adverse events such as bone mineral density (BMD) loss and vasomotor symptoms.

BEYOND THE BOOK

BEYOND THE BOOK

Create a chart comparing and contrasting the use of each class of medications in the following individuals with endometriosis:

17-year-old patient with severe dysmenorrhea

34-year-old patient with dysmenorrhea despite use of combined oral contraceptive

28-year-old patient looking for something to help with pain relief and contraception

43-year-old patient with osteoporosis

31-year-old patient with no insurance

INTRODUCTION

① Endometriosis is a common gynecologic condition that affects females during their reproductive years, defined as the growth of endometrial tissue outside the uterus. Clinically, endometriosis can cause several symptoms with the most common being dysmenorrhea, dyspareunia, and infertility. It is usually diagnosed in individuals in their thirties and forties; however, it is also common in adolescent age. Chronic pelvic pain is the most common complaint, especially in adolescents. Patients are often asymptomatic; therefore, it is difficult to confirm the true incidence of endometriosis. Similar to other chapters in this section, general discussions around endometriosis and its treatment are primarily framed around cisgender women. However, any individual with a female reproductive system may experience endometriosis. Therefore, the use of the term *female* is specifically meant to refer to biology, and this chapter has been written to include transgender individuals.

While the pathophysiology of endometriosis is not completely understood, it is believed that retrograde menstrual flow causes several endometriosis symptoms. This backflow of fluid often leads to endometrial deposits in various areas of the genitourinary tract including the bladder, ureter, and ovaries in addition to the gastrointestinal tract. Other theories include hematogenous or lymphatic transport, stem cells from bone marrow, and coelomic metaplasia Interventions are focused on the desire of the patient to become pregnant, relieve symptoms, or both. Pregnancies are often beneficial for improving symptoms.

EPIDEMIOLOGY

The incidence of endometriosis in the general population is approximately 10%.[1,2] It is a common cause of infertility and chronic pelvic pain and has an incidence of approximately 38% in females with infertility (with some estimates of around 50%); and more than 60% of patients with chronic pelvic pain have a diagnosis of endometriosis (with some reports of 71%-87%).[2] Roughly one in 10 females of reproductive age are diagnosed with endometriosis. However, it is probable that approximately 11% of individuals are undiagnosed. There is a strong genetic predisposition, and it has been noted that females with a first degree relative with endometriosis have a seven- to 10-fold increased risk for developing endometriosis.[2]

ETIOLOGY

Endometriosis is characterized by the growth of endometrial tissue outside of the uterus[1,2]; and while it can be diagnosed in any age, it is most commonly found during the reproductive years. In addition to genetic predisposition, several risk factors have been identified. The risk of endometriosis is higher in those with early menarche (defined as the start of menses at 11 years old or younger), short menstrual cycles (<27 days), and heavy, prolonged menses. The environmental factors play a role in the pathogenesis of endometriosis. For example, dioxins, chemicals that have been found in the environment, have been thought to increase the risk for developing endometriosis or worsening symptoms.[3,4] Multiple parity has been associated with a lower risk of endometriosis and/or improvement in endometriosis symptoms. Additionally, regular exercise of more than 4 hours per week has been associated with a lower risk of the development of endometriosis.[2,5]

In addition to infertility and chronic pain, endometriosis is a major cause of hysterectomy and hospitalization in the United States and can lead to decreased quality of life.

PATHOPHYSIOLOGY

2 While not well understood, the pathophysiology of endometriosis is related to the finding of endometrial implants (the tissue forming the lining of the uterus) outside of the uterus. These implants occur outside of the uterus due to retrograde menstrual flow. Endometrial implants are often found in the peritoneum, ovaries, fallopian tubes, uterus, bladder, ureters, intestines, and rectum.[6,7] The growth of implants is dependent on estrogen, and throughout the menstrual cycle they grow and bleed just as the endometrium thickens and sheds during menstruation. When the implants proliferate, adhesions (collections of scar tissue) can form that can lead to further bleeding, inflammation, and scarring especially prior to and during menses.

While retrograde menstruation can explain the endometrial deposits in the peritoneal cavity, there are also other theories regarding the development of endometriotic implants. Additionally, some have retrograde menstruation, yet do not develop endometriosis. There is a 90% prevalence of retrograde menstruation, yet 10% prevalence of endometriosis.[8] Four well-supported hallmarks of the pathophysiology of endometriosis include genetic predisposition, estrogen dependence, progesterone resistance, and inflammation.[6–10]

In patients with endometriosis, there are alterations in estrogen- and progesterone-dependent processes including inflammatory and immune responses, angiogenesis, and apoptosis. These alterations lead to survival and replenishment of endometriotic tissue. Genetic alterations that have been noted include the upregulation of B-cell lymphoma 2 (*BCL-2*), which is an antiapoptotic gene and is present in both eutopic and ectopic endometrium from patients with endometriosis.[8] An observation in endometriotic tissue showed the increased expression of the aromatase enzyme and decreased expression of 17β-hydroxysteroid dehydrogenase (17β-HSD) type 2, which leads to an increase in the concentration of estradiol. Estradiol stimulates prostaglandin E2 that further can stimulate aromatase activity. Estrogen can stimulate the release of other inflammatory cytokines such as cyclooxygenase 2 (COX-2). Additionally, endometriotic lesions have decreased progesterone receptor expression and an absence of progesterone receptor-B. This can lead to an incomplete transition of endometrium from the luteal phase to the secretory phase of the menstrual cycle. While estradiol tends to have proinflammatory and antiapoptotic effects on endometrial cells, progestins inhibit inflammatory pathways and induce apoptosis in endometriotic cells.

Endometriosis has been considered a pelvic inflammatory condition because the peritoneal fluid tends to contain several inflammatory markers that are believed to contribute to pain, formation of adhesions, tissue fibrosis, and scarring. In patients without endometriosis, the immune system clears refluxed endometrial tissue deposits from the peritoneum. Endometrial lesions can lead to inflammation with the activation of macrophages and proinflammatory cytokines. The peritoneal fluid of patients with endometriosis often contains proinflammatory cytokines such as tumor necrosis factor alpha and interleukins 1, 6, and 8 that lead to prostaglandin induction. There is also an increased density of nerve fibers and a high expression of nerve growth factor in endometriotic lesions which further increases pain. Compression of nerve fibers by endometrial implants along with bleeding from endometrial tissues can increase a patient’s pain. Lastly, endometriotic nerve fibers influence dorsal root neurons thereby increasing pain perception.

Infertility and the reason for its development have been less well described, especially in mild cases of endometriosis. In more severe cases, inflammation and anatomic abnormalities such as ovarian cysts and adhesions can lead to blockage of the fallopian tubes and hindrance of oocyte and embryo development. The inflammatory cytokines can lead to damage of sperm DNA and cell membranes and the general inflammation seen may result in adhesions and scarring.[1] Hormonal dysregulation can also lead to irregularities in the menstrual cycle, alterations in endometrial receptivity and implantation, and altered oocyte and embryo quality, or issues with uterotubal transport.[8]

CLINICAL PRESENTATION

Symptoms

3 Endometriosis presents in a variable and unpredictable manner with regard to clinical presentation and clinical course. Dysmenorrhea and infertility are the most commonly reported symptoms in patients; however, several other symptoms are often present, or a patient can remain asymptomatic. Typical symptoms include abdominopelvic pain, dysmenorrhea, and dyspareunia; and those experiencing these classic symptoms are more likely to be diagnosed than those presenting without these symptoms. Deep pain during or after sexual intercourse, period-related or cyclical

gastrointestinal symptoms, such as painful bowel movements, menorrhagia, ovulation pain, and chronic fatigue are other possible symptoms. Chronic pelvic pain can vary in severity and may be cyclic or acyclic. Pain can lead to a decreased quality of life depending on the severity; however, some patients may be asymptomatic.[2,6,7]

Signs

Physical examination of a patient with endometriosis often reveals pelvic tenderness, enlarged ovaries, pelvic masses or nodules, uterosacral ligaments, or a fixed, retroverted uterus. These signs are usually most significant during menses, so it is recommended to perform the examination at that time. Imaging studies such as transvaginal ultrasound or magnetic resonance imaging are also used to visualize endometrial lesions. If a patient with suspected endometriosis has normal imaging studies, laparoscopic surgery can be considered to further evaluate the pelvis and endometrial lesions. Lesions can vary in size from small lesions in the ovaries or peritoneum to endometriomas, which are large cysts. The lesions are often described as “powder burn” or “gunshot” lesions; dark brown, black or blue lesions, nodules, and cysts; and blood containing endometriomas are called “chocolate cysts.”[11]

CLINICAL PRESENTATION: Endometriosis

Physical Symptoms

- Dysmenorrhea
- Infertility
- Pelvic pain
- Dyspareunia (Deep pain during or after sexual intercourse)
- Menstrual cycle-related or cyclical gastrointestinal symptoms (eg, painful bowel movements)
- Menorrhagia
- Ovulation pain
- Chronic fatigue are other possible symptoms

Other considerations

- Chronic pelvic pain can vary in severity and may be cyclic or acyclic
- Pain can lead to a decreased quality of life depending on the severity
- Some patients may be asymptomatic

Signs: From physical examination of a patient with endometriosis

- Pelvic tenderness
- Enlarged ovaries
- Pelvic masses or nodules
- Uterosacral ligaments
- Fixed, retroverted uterus
- *Note: These signs are usually most significant during menses*

Data from References 2,6, and 7.

Diagnosis

④ The diagnosis of endometriosis can be challenging and may take several years due to variability of symptoms. Additionally, a definitive diagnosis can only be made by histological examination of lesions removed during surgery. Treatment guidelines do discuss ruling out all causes of pain and providing a nondefinitive diagnosis in patients with chronic pelvic pain. Ultrasonography, magnetic resonance imaging, and computed tomography are often used to assess pelvic or adnexal masses, but have a lower sensitive for investigating endometrial lesions. However, in some cases pelvic and abdominal examinations can be used, especially during menstruation and positive findings include pelvic tenderness, enlarged ovaries, or a fixed, retroverted uterus. Imaging studies can be utilized to determine whether there is endometrial tissue in the bowel, bladder, or ureter. Transvaginal ultrasounds are used to determine if endometrial tissue is infiltrating the rectum. Cancer antigen 125 (CA-125) is a marker for ovarian and endometrial cancer, which has been noted to be elevated in some patients with endometriosis but is not a diagnostic marker.[11] However, for diagnosis of endometriosis, the CA-125 measurement is limited due to the fact that an elevated level is not diagnostic.[2,11]

Disease Staging

In general, endometriosis disease severity can be classified according to the American Society of Reproductive Medicine (ASRM) staging system which ranges from stage I (mild) to stage IV (severe). This system stages endometriosis according to not only anatomic location but also the severity of disease.[2] Although staging of disease can be helpful, it is limited in its clinical utility because it does not predict pregnancy after treatment and does not correlate well with symptoms of pain or dyspareunia.[2] Regardless, staging may be useful in guiding decisions regarding prognosis and treatment for infertility.[2,12]

TREATMENT

Multiple guidelines and expert opinions exist for the management of endometriosis, with key guidelines coming from organizations such as the American College of Obstetricians and Gynecologists (ACOG), the American Society for Reproductive Medicine, Society of Obstetricians and Gynecologists of Canada, National Institute for Health and Care Excellence,[11] and the European Society of Human Reproduction and Embryology (ESHRE).[12,13] Table 101-1 is a summary of the ESHRE-graded recommendations.

TABLE 101-1

Evidence-Based Recommendations for Treatment of Endometriosis-Related Pain

Treatment Options	Grade of Recommendation—ESHRE
CHCs	
Oral	B
Vaginal	C
Transdermal	C
Continuous use of CHC	C
Progestins	
Oral	A
Depot	A
LNG-IUS	B
Danazol	A
GnRH Agonist	A
Initiate add-back therapy with GnRH agonist initiation to prevent anti-estrogen adverse effects	A
NSAIDs	GPP
Aromatase inhibitors (in patients in refractory endometriosis, used in combination with oral CHCs, progestins, GnRH agonists)	B
Surgical Treatment	A

ESHRE, European Society of Human Reproduction and Embryology; CHC, combined hormonal contraceptive; LNG-IUS, levonorgestrel-releasing intrauterine system; GnRH, gonadotropin-releasing hormone; NSAID, nonsteroidal anti-inflammatory drugs.

A = Meta-analysis or multiple randomized trials (of high quality); B = Meta-analysis or multiple randomized trials of moderate quality, single randomized trial, large nonrandomized trials, or case-control/cohort studies of high quality; C = Single randomized trial, large nonrandomized trial(s), or case-control/cohort studies (of moderate quality); D = Nonanalytic studies or case reports/case series (of high or moderate quality); GPP = Good practice point based on expert opinion.

Data from Reference 12.

Desired Outcomes

⑦ ⑤ Endometriosis is not curable with available treatment modalities; therefore, the present available options allow for the management of disease primarily through pain relief and correction of infertility treatment. Patient-specific goals and desired outcomes will vary and should be considered when making a treatment plan, as the individual patient's desires will greatly impact the treatment options available. Reducing pain and improving quality of life can be achieved through pharmacologic options and/or surgery.[2,10,14] Endometriosis-related infertility does not respond to available pharmacologic therapies and requires surgical intervention.[2,10]

General Approach to Treatment

Endometriosis-related pain can be managed with medical treatment, surgical treatment, or both. The best option for an individual patient will depend on their specific goals for treatment. Current medical therapies relieve endometriosis-related pain through induction of a pseudopregnancy or pseudo menopausal state, which reduces painful lesions, but does not improve fertility. Therefore, individuals looking to become pregnant will typically require surgical intervention and may also require the use of assisted reproductive technologies. Pregnancy success rates do increase after surgical procedures, but the exact magnitude is unclear due to the lack of well-designed clinical studies.[2,10,14]

Medical management options include nonsteroidal anti-inflammatory drugs (NSAIDs), combined hormonal contraceptive (CHCs), progestins, gonadotropin-releasing hormone (GnRH) agonists, GnRH antagonists, danazol, and aromatase inhibitors. In general, the NSAIDs, CHCs, and progestins are recommended first line due to their proven success in dysmenorrhea management, tolerability, and cost. The GnRH agonists and danazol are both highly effective but are considered second-line options because of their adverse effect profiles. Aromatase inhibitors are considered last line after failure of other medical or surgical therapies.

The patient's chief complaint, possible adverse effects seen with various pharmacotherapeutic agents, extent of prescription medication coverage, contraindications to treatment, and adherence should all be considered when developing a treatment plan.[2,10,12,15] Information regarding pharmacotherapy options can be seen in Table 101-2. The NSAIDs are appropriate to use in conjunction with each listed treatment option, barring the existence of contraindications to use, as endometriosis treatments are not typically guaranteed to provide full relief of symptoms and may require adjunctive analgesic use.

TABLE 101-2

Evidence-Based Considerations in Endometriosis Treatment

Treatment Considerations	Grade of Recommendation—ESHRE
Empirical treatment of pain (without specific diagnosis) with CHCs or progestins	GPP
Preoperative hormonal treatment should NOT be initiated prior to surgery with the primary goal to improve surgery outcomes	A
Postoperative hormonal treatment should NOT be initiated after surgery with the primary goal to improve surgery outcomes	A
CHCs and LNG-IUS are preferred treatment options for postoperative secondary prevention of dysmenorrhea	A
Operative laparoscopy is the preferred treatment option for patients with infertility secondary to endometriosis who are looking to become pregnant	A
Hysterectomy–oophorectomy may be considered in patients finished with childbearing who have failed more conservative options	GPP

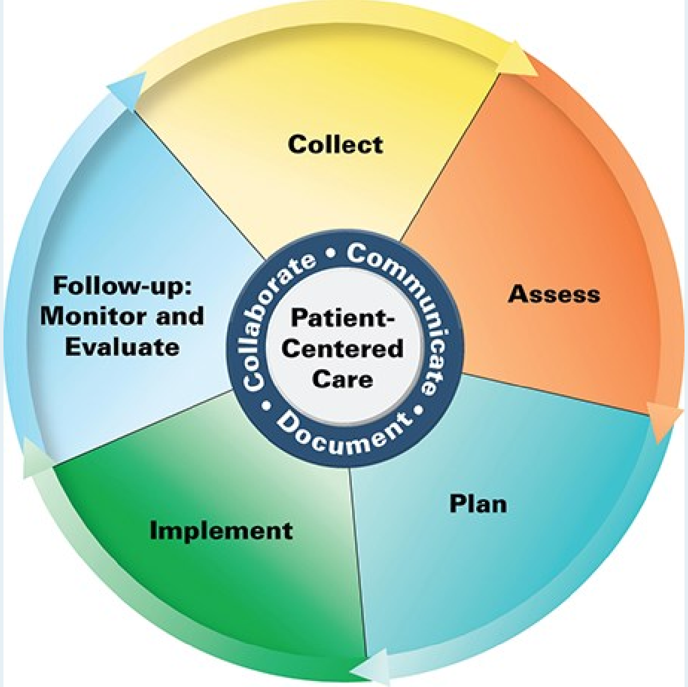
A = Meta-analysis or multiple randomized trials (of high quality); B = Meta-analysis or multiple randomized trials of moderate quality, single randomized trial, large nonrandomized trials, or case-control/cohort studies of high quality; C = Single randomized trial, large nonrandomized trial(s), or case-control/cohort studies (of moderate quality); D = Nonanalytic studies or case reports/case series (of high or moderate quality); GPP = Good practice point based on expert opinion.

Data from Reference 12.

Asymptomatic patients with an incidental diagnosis of endometriosis do not need treatment, but rather can be monitored for the development of pain or infertility and then managed at that point.[12]

PATIENT CARE PROCESS

Patient Care Process for Endometriosis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (age, race, ethnicity, sex, gender identity, pregnancy status, and interest in becoming pregnant)
- Patient medical history (personal and family)
- Patient's desire and timeline for fertility
- Symptoms (type of pain, location, frequency, cyclic vs acyclic)
- Objective data
    - Imaging procedure results confirming diagnosis of endometriosis (if available)

Assess

- Whether patient is a candidate for pharmacotherapy or surgical procedures
- Patient goals and treatment options (Tables 101-1 and 101-2)
- Presence of contraindications to treatment options
- Ability/willingness to use various formulations such as injections, vaginal ring, transdermal patch, intrauterine device
- Ability/willingness to pay for treatment options
- Likely adherence to options

Plan*

- Pharmacotherapy regimen including specific medication(s), dose, route, frequency, and duration (Table 101-3)
- Monitoring parameters including efficacy and safety (pain relief, adverse medication effects) (Table 101-3)
- Prepare patient education

- Referrals to other providers

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up appointment (typically 2-3 months to determine treatment efficacy)

Follow-Up/Monitor

- Resolution of symptoms
- Presence of adverse medication effects (Table 101-3)
- If using GnRH agonists: bone mineral density and serum lipids
- Patient adherence to treatment plan
- Duration of therapy depending on desire to become pregnant or patient entering menopause

Collaborate with patients, caregivers, and other healthcare professionals.

Nonpharmacologic Therapy

⑥ Laparoscopic surgery is used as a diagnostic and therapeutic tool for endometriosis.[2,10,12] As part of this procedure, surgeons remove any visible lesions when performing a diagnostic surgery. Otherwise, individuals may seek surgery if they are infertile or are not responding to available medical treatment options. A hysterectomy–oophorectomy is an option for individuals who do not desire future pregnancy, but, as with other treatment modalities, this surgery does not guarantee full relief of symptoms.[12]

For those undergoing surgery, pre- and posttreatment with hormone therapy does not improve outcomes related to surgery. The ESHRE guidelines separate postsurgical treatment into adjunctive (use for <6 months) and secondary prevention (use for >6 months) categories. These guidelines state that short-term adjunctive hormonal treatment will not improve the surgical outcomes after surgery, but long-term medical treatment may be started postsurgery for purposes of contraception or secondary prevention. Secondary prevention recommendations include using CHCs or the levonorgestrel-releasing intrauterine system (LNG-IUS) for at least 18 to 24 months to prevent recurrence of endometriomas.[12,16,17]

Pharmacologic Therapy

Pharmacologic therapy is typically the first choice for treatment of endometriosis-related pain to minimize risks from multiple surgeries such as scarring and tissue adhesions. First-line treatment options are such because they are equally effective but have an improved tolerability and cost compared to alternative therapy options (Table 101-3).[2,10,12,15]

TABLE 101-3

Dosing, Adverse Effects (AE) Monitoring, and Comments

Pharmacotherapy Options	Brand Name	Dosing	Adverse Effects	Monitoring Parameters and Counseling Points
NSAID				

Ibuprofen	Motrin; Advil	200-800 mg orally 3 times daily	Gastrointestinal upset, dizziness, skin rash, tinnitus	Take with food to limit GI upset
Naproxen	Aleve, Naprosyn	200-220 mg orally 2-3 times daily up to 500-550 mg twice daily		Consider monitoring blood pressure if using regularly
Diclofenac	Voltaren	50 mg orally 3 times daily		
CHC				
Various (oral tablet)	Various	1 tablet orally daily	Nausea, vomiting, breast tenderness, weight gain, acne, oily skin, fatigue, breakthrough bleeding, spotting, elevated blood pressure, application site reaction (patch only), vaginal irritation (ring only)	Continuous dosing may improve outcomes
Etonogestrel/ethinyl estradiol (vaginal ring)	NuvaRing	Insert 1 ring vaginally for 3 weeks and remove for 1 week		Many AEs improve after 2-3 cycles
Norelgestromin/ethinyl estradiol (transdermal)	Ortho Evra; Xulane	Apply one patch weekly for 3 weeks and remove for 1 week		Measure blood pressure within 3 months of starting new method
Progestin				
Norethindrone (oral tablet)	Aygestin	5 mg orally daily; may titrate to 20 mg daily	Breast tenderness, nausea, peripheral edema, VTE	
MPA (oral tablet)	Provera	30 mg orally daily; may titrate to 60 mg daily	Menstrual irregularities, nausea, peripheral edema, VTE	
DMPA (IM or SubQ)	Depo-Provera IM	150 mg IM every 13 weeks	Menstrual irregularities, weight gain, acne, hirsutism, depression, decreased BMD	BMD testing not recommended
	Depo-SubQ Provera	104 mg SubQ every 12-14 weeks		
LNG-IUS	Mirena	Single insertion for up to 5 years	Menstrual irregularities, insertion-related complications, expulsion, pelvic inflammatory disease	
GnRH Agonist				
Goserelin	Zoladex	3.6 mg monthly SubQ implant	Acne, depression, hot flashes, mood swings, peripheral edema, vaginitis, BMD loss	Use add-back to prevent many AEs
Leuprolide	Leupron Depot	3.75 mg IM monthly or 11.25 mg IM every 3 months	Acne, depression, hot flashes, mood swings, vaginitis, BMD loss, VTE, anaphylaxis, nausea/vomiting, headache, dizziness, triglyceride elevation	Consider BMD testing every 1-2 years and serum lipid levels every 6 months if treatment exceeds 12 months

Naferelin	Naferelin	400 mcg intranasally daily (one spray in one nostril AM and one spray in the opposite nostril PM); may titrate to 800 mcg daily	Acne, headache, hot flash, mood swing, vaginal dryness, BMD loss, VTE	
Triptorelin	Triptorelin	3.75 mg IM monthly	Headache, elevated blood pressure, hot flashes, anaphylaxis, angioedema	
GnRH Antagonist				
Elagolix	Orilissa	150 mg orally once daily or 200 mg orally twice daily	Headache, nausea, anxiety, hot flash, BMD loss, change in lipid levels, insomnia, mood swings, night sweats	
Androgen				
Danazol	Danocrine	100-200 mg orally twice daily; may titrate to 400 mg twice daily	Acne, peripheral edema, hirsutism, lipid abnormalities, weight gain, hepatic dysfunction	Liver function tests and serum cholesterol every 3-6 months
Aromatase Inhibitor				
Anastrozole	Arimidex	1 mg orally daily	Arthralgias, hot flashes, myalgias, nausea, diarrhea, decreased BMD	Use with CHC, progestin, or GnRH agonist
Letrozole	Femara	2.5 mg orally daily		Consider BMD testing every 1-2 years if treatment exceeds 12 months

AEs, adverse effects; BMD, bone mineral density; DMPA, depot medroxyprogesterone acetate; IM, intramuscular; MPA, medroxyprogesterone acetate; SubQ, subcutaneous; VTE, venous thromboembolism.

Medication Treatments of First Choice

⑧ First-line therapy for endometriosis-associated pain includes oral CHCs, oral progestins (norethindrone acetate or medroxyprogesterone acetate [MPA]), or depot medroxyprogesterone acetate (DMPA). These medications tend to be well-tolerated and are safe for long-term use, which is important because endometriosis symptoms typically return shortly after treatment is discontinued.[2,10,12,15]

Studies demonstrating direct comparisons between these products are lacking, so the decision of which product to use should depend on patient preference, including formulation type, dosing schedule, and potential adverse effects.[2]

Although laparoscopic imaging provides the only definitive diagnosis of endometriosis, these options may be initiated empirically for suspected endometriosis in patients of any age prior to laparoscopy.[2,10,12,15] Response to hormonal treatment does not predict the presence or absence of endometriosis, but use of these options before laparoscopy can avoid an invasive procedure.[12]

Nonsteroidal Anti-inflammatory Drugs

Dysmenorrhea is a primary symptomatic feature of endometriosis and NSAIDs are indicated as the first-line treatment of menstrual pain with or without an endometriosis diagnosis. Individuals may initially self-treat with over-the-counter options, such as ibuprofen and naproxen; however, prescription strength versions of these are available as well, and individuals may find they need to use the upper end of the recommended dosing range in order to find relief from pain.[2,10,11]

Combined Hormonal Contraception

CHCs are a first-line treatment option for suppression of endometriosis and are widely used due to their efficacy, tolerability, safety profile, and cost.[18] Their exact mechanism of action for endometrial pain relief is unclear because the pathogenesis of endometriosis is unclear. However, there are several widely accepted theories.[18] The CHCs alleviate dysmenorrhea, a common symptom of endometriosis, reduce the growth of endometrial tissue, decrease menstrual flow, and reduce prostaglandin generation.[18] They also downregulate cell proliferation and increase apoptosis in the eutopic endometrium.[18] Secondary benefits of CHCs include menstrual cycle regulation and contraception.

Oral CHCs have efficacy in a small number of observational, placebo-controlled, and active-comparator trials. The majority of studies on CHC efficacy have been for oral products; however, one study proved effectiveness of the CHC patch and vaginal ring, which may have appealing dosing schedules compared to their oral counterparts.[19] The decision between CHCs should be based upon patient preference, including adherence and cost.[2]

The CHCs have traditionally been dosed cyclically, with 3 weeks of active hormone followed by 1 week of placebo, allowing for a withdrawal bleed. However, some individuals prefer the option to dose continuously, either through commercially available “extended cycle” options or by skipping the placebo week of their CHC. The continuous dosing may be more efficacious than cyclic dosing after individuals with recurrent postoperative dysmenorrhea were switched from cyclic to continuous CHC dosing and reported a significant reduction in pain.[20] Other studies have mimicked these results, and the ESHRE guidelines now specifically recommend continuous dosing as an option for patients.[12]

Due to the proposed estrogen dependency of endometriotic lesions, it has been proposed that the estrogen dose in CHCs should be limited to avoid feeding the endometriosis tissue. Even the lowest doses of commercially available CHCs are four to six times the physiologic dose of estrogen; therefore, clinicians should consider initiating patients on CHCs with the lowest effective estrogen dose to limit this possibility.

Progestins

Progestins are another first-line option for suppression of endometriosis due to their efficacy in treating dysmenorrhea, the overall tolerability of progestins, and their reasonable price. Progestins suppress growth of endometriotic implants, eventually causing endometriotic atrophy. They have also demonstrated inhibition of blood vessel growth and anti-inflammatory action, in addition to their anovulatory effects, all which relieve the dysmenorrhea associated with endometriosis.[21–23]

Progestins may be administered orally (norethindrone acetate or MPA), intramuscularly or subcutaneously (DMPA) or as an LNG-IUS. As with other endometriosis treatment options, studies comparing progestin options directly are limited; therefore, selection should account for the individual’s opinion about dosage form, as well as cost and potential adverse effects and risks.[24]

Oral Progestins

Oral progestins are widely available as contraceptive and menopausal hormonal replacement products. Importantly, contraceptive progestin products have the added benefit of preventing pregnancy and managing other menstrual-related adverse effects, such as acne.

Injectable Depot Medroxyprogesterone Acetate

The downsides to injectable DMPA use include a slow return to fertility and potential bone mineral density (BMD) loss, as DMPA carries a black box warning to avoid use for greater than 2 years due to the risk of potentially irreversible BMD loss. Controversy exists on the potential irreversibility of BMD loss and despite this labeling, the ACOG has stated that clinicians may continue its use beyond 2 years in patients who are responding well.[25] For those who wish to become pregnant shortly after discontinuing treatment, this option may not be preferred because of its associated slow return of normal ovulation. DMPA has a mean conception time of 10 months after discontinuation, compared to other hormonal products that have shorter return to fertility.[26]

Levonorgestrel Intrauterine System

Insertion of an LNG-IUS is an option for those seeking long-acting reversible contraceptive benefits in addition to endometriosis pain relief. There are various forms of LNG-IUSs available in the market. Approximately 20% to 30% of patients experience amenorrhea within the first year of using an LNG-IUS, reducing the major symptom of endometriosis, dysmenorrhea.[27] Despite their efficacy at reducing endometriosis-related pain, no LNG-IUSs are Food and Drug Administration (FDA) approved for the treatment of endometriosis.

The LNG-IUSs do not inhibit ovulation, yielding a potential for the growth of ovarian endometriomas. Other disadvantages of the LNG-IUS include potential difficulty of inserting the device into nulliparous individuals, a 5% expulsion rate, and cost of the procedure.[15]

Alternative Medication Treatments

Other options for treatment of endometriosis pain include GnRH agonists, GnRH antagonists, danazol, and aromatase inhibitors.[2,12,15,28] Treatments fall into this category for several reasons: lack of data supporting their efficacy in treating endometriosis, proven efficacy but intolerable adverse events, or unknown long-term safety.

None of these methods is proven superior over others, so treatment decisions should be made based on patient preference of dosage form and dosing schedule, patient-specific response, potential adverse effects, and medication costs/insurance coverage.[2,10,12,15]

Several of the options in this category can be combined with other medications to limit their adverse effects. For example, GnRH agonists are used with estrogen-progestin products to limit anti-estrogenic adverse effects and aromatase inhibitors are prescribed with CHCs, progestins, or GnRH agonists.

Gonadotropin-Releasing Hormone Agonists

The GnRH agonists are highly effective at treating endometriosis-associated pain, but their use is limited by adverse effects and cost. The ACOG guidelines recommend their empiric use in the event of NSAID or contraceptive failure.[2] Pharmacologically the GnRH agonists inhibit follicle-stimulating hormone and luteinizing hormone secretion, which effectively mimics an oophorectomy.

The GnRH agonists create a gonadotropic flare prior to their long-term receptor downregulation, which may increase pain during this period. This can be minimized by initiating therapy during the mid-luteal phase or overlapping therapy with a CHC or progestin for 3 weeks. Pain will recur quickly upon discontinuation, making GnRH agonists a chronic treatment option.[29,30] Although GnRH agonist are approved by the FDA for only 12-month courses of treatment, if a patient responds well to therapy, it is often continued for longer with add-back therapy (subsequently discussed).[2]

Adverse medication effects seen with GnRH agonists are the result of the hypoestrogenic environment and include BMD loss and vasomotor symptoms, such as hot flushes, vaginal dryness, and insomnia. With long-term use (>6 months) BMD loss becomes a major concern. Utilization of add-back therapy minimizes this loss and other adverse events and has demonstrated safety for up to 10 years.[31,32] It is recommended to start add-back therapy on immediate initiation of GnRH agonist treatment.[2,12,15] Monitoring for this class of medications includes physical findings, bone density, and serum lipids.[2]

Add-Back Therapy

⑨ Add-back regimens may consist of progestins alone, estrogens, and progestins and bisphosphonates and are utilized in combination with GnRH agonists to reduce or eliminate BMD loss and provide symptomatic relief against the anti-estrogenic effects of GnRH agonists. The estrogen-progestin combinations are more effective than progestin monotherapy at protecting for BMD loss.[30,33,34]

Adding estrogen to a GnRH agonist has a potential to negate its anti-estrogenic effects that relieve endometriosis pain. Therefore, the dose of estrogen must be low enough to maintain a serum estrogen level <50 pg/mL (180 pmol/L) in order to prevent growth of new endometrial tissue while preventing anti-estrogenic adverse effects such as BMD loss and vasomotor symptoms. The CHCs should not be used as add-back therapy because they will yield a higher serum level than recommended; therefore, menopausal preparations are typically appropriately dosed to reach this serum level.[15] Examples of regimens studied include oral conjugated equine estrogens 0.625 mg/day plus oral norethindrone acetate 5 mg/day, and transdermal estradiol 25 µg twice weekly plus oral MPA 5 mg/day, and oral estradiol 2 mg/day plus oral norethindrone acetate 1 mg/day.[33]

Gonadotropin-Releasing Hormone Antagonists

Elagolix is the only FDA-approved medication indicated to treat endometriosis. It is a member of the class of GnRH antagonists, which competitively inhibit GnRH receptors in the pituitary in order to rapidly decreases circulating estradiol and gonadotropins.[35] GnRH antagonists may represent a class of medications with similar efficacy but better tolerability compared to the GnRH agonists: while effectively downregulating the same hormones as GnRH agonists, the GnRH antagonists differ in their quicker onset and avoidance of a painful gonadotropin flare upon initiation. Elagolix can be dosed to achieve partial or full suppression, which may minimize hypoestrogenic adverse events compared to GnRH agonists. It is not clear whether add-back therapy is appropriate to minimize these adverse events if they do occur.

Adverse effects of elagolix include headache, nausea, anxiety, hot flashes, and some breakthrough bleeding and spotting.[36] Hypoestrogenic effects include hot flashes, increased serum lipid levels, and BMD loss. It is unknown whether the BMD loss is reversible and what the long-term effects of use may be.

Elagolix does not fully suppress ovulation and the effect of GnRH antagonists on pregnancy is unknown now.[36] Individuals are recommended to use contraception to avoid pregnancy while on this class of medications until further information is known.

Androgens

Danazol is an androgen that serves as a second-line hormonal treatment option. Danazol inhibits endometrial tissue growth, induces endometrial atrophy, and causes amenorrhea due to the hypo-estrogenic/hypo-progestogenic environment it creates. It is highly effective and was formerly considered the gold standard of endometriosis treatment but is now used in a limited manner because of the androgenic properties of its adverse medication effect profile.[37]

Danazol should not be initiated in individuals with hyperlipidemia or liver disease. Barrier contraception must be used in conjunction with use of this medication due to its teratogenicity. Common adverse medication effects include hirsutism, mood changes, voice deepening, and acne, although some individuals may experience significant weight gain and fluid retention.[37]

Three studies have looked at the use of vaginal danazol formulations in an effort to limit systemic medication exposure and limit androgenic effects. Each study proved improvements in dysmenorrhea, deep dyspareunia, and pelvic pain without systemic adverse effects. The vaginal formulation of danazol is notavailable in the United States.[38–40]

Aromatase Inhibitors

Aromatase inhibitors are a more recent addition to the endometriosis-treatment toolkit. While the ACOG guidelines do not support their routine use based on limited data, the ESHRE guidelines support their use in individuals with endometriosis refractory to other medical or surgical treatment.[2,12] This class lowers overall estrogen concentrations by inhibiting aromatase, which is key enzyme in the conversion of adrenal androgens to estrogens. The resultant reduction of estrogen concentrations then diminishes endometrial lesions.

Numerous case reports and studies have looked at aromatase inhibitors in combination with progestins, oral CHCs and GnRH agonists. Based on the results of these studies, there is decreased pain, improved quality of life, and reduced postoperative recurrence of disease in patients refractory to other treatments.[40–44]

As the aromatase inhibitors reduce circulating estrogen levels, long-term use may impact BMD, similar to other pharmacologic therapies. Safety information for this class of medications is mainly from studies in postmenopausal patients with cancer, which differs from the typical female of reproductive age who would be using these agents for endometriosis pain. Limited available data does indicate that the use of progestin monotherapy or CHCs in addition to the aromatase inhibitor would limit BMD loss.[40,41] The progestin and combined oral contraceptives may also limit the follicle-stimulating hormone release, which may lead to chronic ovarian stimulation.[2]

Special Populations

Endometriosis is most commonly diagnosed in individuals in their thirties and forties, but endometriosis is the most common diagnosis in adolescent patients presenting with secondary dysmenorrhea.[15] Endometriosis commonly presents as early stage in adolescents, so physical findings will often be normal and laparoscopic findings may be atypical compared to those seen in older individuals.[15]

Treatment of adolescent patients is similar to adult treatment guidelines, with the most notable difference related to the use of options that affect BMD.[15,28,45] Both DMPA and the GnRH agonists should be used with caution in adolescents due to BMD loss concerns and while they are not completely contraindicated, their use should be held off as long as possible and only started after full consideration of the risk/benefit profile.[45]

Dysmenorrhea in adolescents is typically treated empirically with first-line options including NSAIDs and CHCs. These can be trialed for 3 months to assess pain relief. If pain persists after 3 months, CHCs may be switched from cyclic to continuous dosing to instigate amenorrhea. The next step after failure of this first-line option typically includes consideration of laparoscopic diagnostic/treatment surgery because failure correlates highly to a diagnosis of endometriosis.

The incidence of endometriosis, pelvic pain, and irregular or heavy menses in transgender individuals has not been well characterized. Endometriosis is likely underdiagnosed in this patient group, but based on recent reports up to 50% of transgender men presenting for gender-affirming hysterectomy reported pelvic pain. Of these, one-third had findings of endometriosis including irregular bleeding and/or heavy menses.[46] Treatments such as progestins, oral contraceptives, danazol, and testosterone can sometimes relieve these symptoms.[47] Importantly, endometriosis symptoms can continue to occur despite the use of testosterone for their transition and thus may necessitate additional suppression. More studies are needed to better understand the clinical presentation and optimal treatment for this patient population.

EVALUATION OF THERAPEUTIC OUTCOMES

Outcome monitoring for endometriosis is based upon subjective relief of symptoms. Factors such as size, number, and distribution of endometrial lesions do not correlate to pain symptoms or potential fertility, limiting the use of objective tests to measure response to treatment.

The Endometriosis Treatment Satisfaction Questionnaire is a patient-reported outcome instrument that was developed and validated to measure patient reported pain before and/or during periods, pain during and/or after sex, endometriosis pain, bleeding and spotting, tolerability, and overall satisfaction using a seven-point Likert scale. Another validated tool is the Medical Outcomes Study Questionnaire Short Form 36 Health Survey (SF-36).[2,48,49]

Medical treatment of endometriosis should relieve endometriosis-related pain within 2 months of initiation. If symptoms are not relieved, individuals may try another medical option and/or surgery.

Surgery is frequently required in endometriosis-related infertility. Individuals must allow 6 months postintervention to try to conceive. If pregnancy is not achieved within this time-span, assisted reproductive technologies are the next line in treatment.

CONCLUSION

①⑤⑦ Endometriosis is a common disease with implications ranging from pain and reduced quality of life to infertility. Treatment modalities are not curative but may be successful at diminishing discomfort and improving quality of life. Treatment plans should be designed while taking into account patient-specific factors and goals.

SELF-ASSESSMENT QUESTIONS

1. Which of the following can increase the risk of endometriosis?
    A. Later age of menarche
    B. Longer menstrual cycles (>30 days)
    C. Prolonged, heavy bleeding during menses
    D. Multiple parity
2. Which of the following is one of the hallmarks of the pathophysiology of endometriosis?
    A. Estrogen resistance
    B. Progesterone dependence
    C. Amenorrhea
    D. Inflammation
3. Endometriosis has been considered a pelvic inflammatory condition because the peritoneal fluid tends to contain
    A. Estrogen.
    B. Dioxins.
    C. Interleukins.
    D. Toxins.
4. The growth of endometrial implants in endometriosis is dependent on
    A. Progesterone
    B. Estrogen
    C. Testosterone
    D. Prostaglandins
5. Which of the following represents a monitoring parameter for danazol?

A. Kidney function test

B. Liver function test

C. Retinal exam

D. Serum estrogen level

6. E.L. is a 37-year-old patient with controlled hypertension, endometriosis, and tension headaches. Current medications include verapamil ER 180 mg daily and ibuprofen 400 mg as needed for tension headaches. This patient smokes 15 cigarettes daily and drinks a glass of wine each night. A few years ago, they had a laparoscopic procedure that reduced most of their pain, but it is returning. They are now interested in medical treatment. Which of the following represents a contraindication to using a combined hormonal contraceptive to treat this patient's endometriosis pain?

A. Controlled hypertension

B. Verapamil use

C. Smoking

D. Tension headaches

7. Which of the following individuals is *NOT* an appropriate candidate to treat with combined hormonal contraceptives?

A. 14-year-old with seasonal allergies

B. 22-year-old with 7-year history of type 1 diabetes

C. 27-year-old looking to become pregnant in the next year

D. 42-year-old with hyperlipidemia

8. E.P. is a 14-year-old adolescent who presents to their family practitioner for follow-up after presenting with severe menstrual pain 6 months prior. At that time, they were prescribed a low-dose combined oral contraceptive pill. Today, E.P. reports pain relief during part of the month, but still experiences pain during the placebo pill week. Based on this information, which of the following options is the best approach now?

A. Change current oral contraceptive to continuous dosing

B. Refer for laparoscopic evaluation

C. Switch therapy to LNG-IUS

D. Switch therapy to subcutaneous leuprolide

9. GnRH agonists, aromatase inhibitors, and depot medroxyprogesterone all share the potential for which common adverse medication effect?

A. Bone mineral density loss

B. Breakthrough bleeding

C. Hot flashes

D. Acne

10. M.M. is a 32-year-old who started using a GnRH agonist 2 months ago to treat endometriosis. Today they report that the treatment has almost completely relieved their pain, but they have been experiencing uncomfortable hot flashes. What would be the most appropriate next step?

A. Add a combined oral contraceptive pill

B. Add a menopausal hormone replacement product

C. Discontinue the GnRH agonist because its effects are long-lasting

D. Switch to letrozole

11. Which of the following is the most appropriate treatment option for a patient with endometriosis who has been trying to become pregnant for 2 years with no success?

A. Celecoxib for 1 month

B. Combined hormonal contraception for 3 months

C. GnRH agonist for 6 months

D. Laparoscopic surgery

12. A.M. is a 28-year-old with endometriosis looking to improve their fertility. They underwent conservative laparoscopic surgery 12 months ago but have not yet become pregnant. What is the recommended next step for A.M.?

A. Continue watchful waiting for 12 more months

B. Start a GnRH agonist

C. Start depot medroxyprogesterone acetate

D. Start assisted-reproductive efforts

13. R.P. is a 21-year-old, unmarried, college student with severe endometriosis pain that has been unresponsive to 6 months treatment with depot medroxyprogesterone. Their past medical history includes asthma, migraine with aura, and anxiety and medications include citalopram 10 mg by mouth daily, fluticasone/salmeterol 100/50 one puff twice a day, albuterol HFA two puffs every 6 hours as needed, and sumatriptan 50 mg by mouth as needed. Which of the following treatment recommendations would be the best option for R.P. to switch to based on the information given?

A. Place an LNG-IUS

B. Start a low-dose combined oral contraceptive pill

C. Start letrozole and oral medroxyprogesterone acetate

D. Start leuprolide, estradiol, and norethindrone acetate

14. Which of the following does *NOT* represent an example of the “Implement” step in the PPCP?

A. Counseling the patient on the possibility of increased pain in the first few weeks after initiating a GnRH agonist

B. Referring a patient looking to become pregnant for a laparoscopic evaluation

C. Using the ABQ instrument to determine that a patient may not be adherent to an injectable regimen

D. Scheduling the patient for a follow-up appointment in 2 months after initiating a new therapy

15. Which of the following represents part of the “Collect” step in the PPCP?

A. Asking the patient about their goals and timeline for becoming pregnant

B. Determining that the patient has a contraindication to CHCs

C. Counseling the patient on vasomotor side effects of GnRH agonists

D. Reviewing liver function tests of a patient taking danazol

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C**. Prolonged heavy bleeding during menses can increase the risk of endometriosis. Late age of menarche, longer menstrual cycles, and multiple parity would be associated with a lower risk of endometriosis (compared to early menarche, shorter cycles, and nulliparity would have a higher risk of endometriosis). See "Etiology" section.

2. **D**. Inflammation is one of the hallmarks of the pathophysiology of endometriosis and is believed to contribute to pain, fibrosis, and scarring. Estrogen dependence and progesterone resistance are considered hallmarks of the pathophysiology of endometriosis (not estrogen resistance and progesterone dependence). Amenorrhea is not thought to contribute to the pathophysiology of endometriosis. See "Etiology" section.

3. **C**. While estrogen, dioxins, and toxins play a role in endometriosis pathophysiology, interleukins are inflammatory markers that are often found in the peritoneal fluid in patients with endometriosis and are thought to contribute to inflammation of the pelvis. See "Clinical Presentation" section.

4. **B**. The growth and proliferation of endometrial implants in endometriosis is dependent on estrogen. Prostaglandins often cause the inflammation. Testosterone and prostaglandins are not associated with proliferation of implants. See "Pathophysiology" section.

5. **B**. Due to its extensive liver metabolism, danazol requires regular liver function monitoring. See "Alternative Drug Treatments" section.

6. **C**. Individuals older than 35 years old who smoke represent an absolute contraindication to use of CHCs. See "Combined Hormonal Contraceptives" section and Chapter 19, "Arrhythmias."

7. **C**. Choices A, B, and D do not include medical contraindications to the use of CHCs. The patient in choice C is looking to become pregnant, so CHCs would not be an appropriate choice. See "Combined Hormonal Contraceptives" and "General Approach to Treatment" sections.

8. **A**. Continuous dosing can be more effective at managing dysmenorrhea symptoms. This patient reports a partial response to treatment, so the most appropriate next step would be to use continuous dosing to limit a regular withdrawal bleed. See Table 101-3.

9. **A**. The GnRH agonists, aromatase inhibitors, and depot medroxyprogesterone all share the adverse medication effect of BMD loss. See Table 101-3.

10. **B**. The GnRH agonists produce a hypoestrogenic state that can lead to adverse effects such as vasomotor symptoms (hot flashes). Adding a low dose of estrogen/progestin is effective at combating these effects. CHC doses are too high and may negate the effect of the GnRH agonist. See "Gonadotropin-Releasing Hormone Agonists" section.

11. **D**. All available medical options are incompatible with pregnancy. The best choice for a patient with endometriosis wishing to become pregnant is laparoscopic surgery. See "Desired Outcomes" section.

12. **D**. If laparoscopic surgery does not yield a successful pregnancy within 6 months, the recommendation is to move to assistive reproductive technology due to the high incidence of infertility in women with endometriosis. See "Evaluation of Therapeutic Outcomes" section.

13. **D**. This patient failed depot medroxyprogesterone and has a contraindication to CHC (migraine with aura), which makes A and B inappropriate options. Letrozole represents a last-line option. Leuprolide is a GnRH agonist and would be the most appropriate next step, in combination with add-back therapy to limit side effects. See "General Approach to Treatment" section.

14. **C**. Determining whether a patient will be adherent falls under "Collect" and "Assess." Answers A, B, and D all represent parts of the "Implementation" step. See "Patient Care Process" section.

15. **A**. The "Collect" step includes gathering information from the patient, including their own goals for treatment. See "Patient Care Process" section.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 102: Post Menopausal Hormone Therapy

Devra K. Dang; Judy T. Chen

KEY CONCEPTS

KEY CONCEPTS

① The decision to use menopausal hormone therapy (MHT) and the type of formulation used must be individualized based on several factors, including personal preference, age, menopause onset, the severity of menopausal symptoms, and the risks of cardiovascular disease, breast cancer, osteoporotic fracture, and venous thromboembolic events (VTE).

② Menopausal hormone therapy is the most effective treatment option for alleviating moderate-to-severe vasomotor symptoms.

③ Cardiovascular disease—including coronary artery disease, stroke, and peripheral vascular disease—is the leading cause of death among females, but MHT should not be used for reducing the risk of cardiovascular disease.

④ The risk of breast cancer associated with MHT is associated with the addition of progestogen therapy to estrogen. Use of estrogen alone does not increase the risk of breast cancer.

⑤ Use of MHT at doses lower than those prescribed prior to the Women's Health Initiative (WHI) study is effective in reducing bone loss and managing menopausal symptoms.

⑥ Use of transdermal MHT is preferred over oral preparations due to lower risk of thrombosis, and possibly stroke and coronary artery disease.

⑦ Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (ie, unopposed estrogen), use of systemic estrogen in individuals with an intact uterus must always be accompanied by progestogen or tissue-selective estrogen complex (estrogen-bazedoxifene) for endometrial protection.

⑧ In individuals experiencing postmenopausal symptoms, initiation of systemic estrogen therapy should generally be limited to those younger than 60 years of age or within 10 years of menopause onset.

BEYOND THE BOOK

BEYOND THE BOOK

Create a table that compares and contrasts the three main formulations of estrogen: oral, transdermal, and vaginal. Suggested characteristics for comparison include name, dose, efficacy in treating symptoms of menopause, and common and major adverse effects. Summarize the major advantages and disadvantages of each formulation.

INTRODUCTION

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity. It is a natural life event, not a disease, as all females undergo menopause, and each experiences it differently. Natural menopause occurs in stages including perimenopause (in the 5th decade), menopause, and postmenopause (1 year after menopause and beyond). Induced menopause can be experienced any time before natural menopause with bilateral oophorectomy (removal of both ovaries) or iatrogenic ablation of ovarian function (eg, chemotherapy, pelvic radiation). Symptoms of menopause can vary widely with induced menopause typically causing more severe symptoms. Due to the variability in duration, severity, and presence of menopausal symptoms, treatment should be individualized with treatment goals and decisions established in a shared decision-making process. In general, discussions around menopause and its treatment are primarily framed around cisgender women. However, any individual with a female reproductive system who has not undergone medical interventions may experience menopause. Therefore, the use of the term female is specifically meant to refer to biology, and this chapter has been written to include transgender individuals.

EPIDEMIOLOGY

The median age at the onset of menopause in the United States is 51 years, but can vary widely from 40 to 58 years.[1] An estimated 6,000 individuals in the United States reach menopause each day, and will spend approximately 40% of their lives in postmenopause.[2] By 2025, the number of postmenopausal individuals will be 1.1 billion worldwide.[1] By definition, menopause is a normal physiologic event that occurs after 12 consecutive months of amenorrhea, so the time of the final menses is determined retrospectively.[3] Individuals who have undergone hysterectomy (removal of the uterus) must rely on their symptoms to estimate the actual time of menopause, but typically occurs a few years earlier than natural menopause.

ETIOLOGY

A nomenclature and staging system for the female reproductive aging continuum was developed at the Stages of Reproductive Aging Workshop (STRAW) in 2001 and revised in 2011 with the STRAW+10 staging system, which is now considered to be the gold standard for characterizing reproductive aging.[3] The menopause transition refers to the span of time including menstrual, endocrine, and symptom changes starting with variation in menstrual cycle length and ending with the final menstrual period (FMP). Postmenopause occurs during the years beyond the FMP with stabilization of hormone levels and limited endocrine changes.

PATHOPHYSIOLOGY

A female is born with approximately two million primordial follicles in their ovaries. During a normal reproductive life span, they ovulate fewer than 500 times; therefore, the vast majority of follicles undergo atresia.

The hypothalamic–pituitary–ovarian axis dynamically controls reproductive physiology throughout the reproductive years. The pituitary is regulated by pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH), produced by the pituitary in response to GnRH, regulate ovarian function. These gonadotropins also are influenced by negative feedback from estradiol and progesterone. Ovarian follicular activity is reflected by the circulating concentrations of sex steroids and by peptide hormones including inhibin, activin, and anti-Mullerian hormone (AMH). Overall, AMH is a product of growing ovarian follicles, which is independent of the hypothalamic–pituitary–gonadal axis. It is a principal regulator of early follicular recruitment from the primordial pool such that the concentration of AMH in blood may also reflect the nongrowing follicle population. In general, AMH concentrations decline with age, starting from 21 years and decrease 5.6% annually; subsequently, the AMH level reaches a precipitous drop and becomes unpredictable 3 to 5 years before menopause onset.[4] While AMH levels may predict the median time to menopause, obtaining levels of AMH, FSH, and estradiol may be best reserved for females seeking fertility. The sex steroids include estradiol, produced by the dominant follicle; progesterone, produced by the corpus luteum after maturation of the dominant ovarian follicle; and androgens, primarily testosterone and androstenedione, secreted by the ovarian stroma. These sex steroids are important for the healthy functioning of many organs, including the bones, brain, skin, and reproductive and urogenital tracts as they act primarily by regulating gene expression.

Physiologic changes associated with menopause are caused by loss of ovarian follicular activity. Since ovarian primordial follicle numbers decrease with advancing age, by the time of menopause, few follicles remain in the ovary. Hence, the postmenopausal ovary is no longer the primary site of estradiol or progesterone synthesis as it secretes primarily androstenedione. In contrast to the acute fall in circulating estrogen at the time of menopause, circulating androgens begin to decline in the decade prior to the average age of natural menopause and closely parallels increasing age. Whether the ovary continues to secrete testosterone after menopause remains controversial.

With advancing age and ongoing follicle loss, a progressive rise in circulating FSH and a concomitant decline in ovarian inhibin-B and AMH are observed.[5] The associated decline in inhibin B results in the loss of negative feedback on FSH. Inside the ovary, low levels of AMH serve to facilitate FSH-stimulated follicle growth and estrogen synthesis and secretion. Eventually, these compensatory hormonal mechanisms are no longer adequate with further follicle loss.[5] Low AMH concentrations, measured at any time in the cycle, predicts diminishing ovarian reserve.[6] Clear elevations in serum FSH with declining AMH are seen in accelerated depletion of the resting follicle pool after the age of 35 years.[5] When ovarian function has ceased, serum FSH concentrations are greater than 40 IU/L (mIU/mL). Menopause is characterized by a 15-fold increase in circulating FSH concentrations compared with concentrations of FSH in the follicular phase of the cycle, a 10-fold increase in LH, and a greater than 90% decrease in circulating estradiol concentrations.[5] During the perimenopause, FSH concentrations may rise to the postmenopausal range during some cycles but return to premenopausal levels during subsequent cycles. Thus, high concentrations of FSH should not be used to diagnose or manage menopause in perimenopausal individuals since frequency and severity of menopause do not correlate with FSH or serum estradiol levels and may be misleading.[7,8] There is a reciprocal relationship between declining inhibin B level and increasing FSH levels. The continuous decline in estradiol level may not reach its nadir until 1 to 2 years after the final menstrual period.[5]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Perimenopause and Menopause

Signs

- Perimenopause: Abnormal uterine bleeding (AUB) as a result of anovulatory cycles (other gynecologic disorders should be excluded).
- Menopause: permanent cessation of menses

Symptoms

- Vasomotor symptoms (hot flashes and night sweats)
- Sleep disturbances
- Mood changes
- New-onset depression
- Problems with concentration and memory
- Arthralgia
- Genitourinary Syndrome of Menopause (GSM): vaginal dryness, burning and irritation of reproductive organs and structures, sexual dysfunction, dysuria, dyspareunia, urinary urgency, recurrent urinary tract infections

Laboratory Tests

- Perimenopause: FSH on day 2 or 3 of the menstrual cycle greater than 10 to 12 IU/L (mIU/mL)
- Menopause: 15-fold increase in FSH (a high FSH is not required to make the diagnosis)

Other Relevant Diagnostic Tests

- Thyroid function tests
- Iron stores
- Serum prolactin
- Lipid profile
- Serum hCG

Perimenopause commences with the onset of menstrual irregularity and ends 12 months after the last menstrual period.[3] Approximately 90% of females have 4 to 8 years of menstrual cycle changes with heavier flow of longer duration before natural menopause occurs.[1] The menstrual cycle irregularity is most often caused by the increased frequency of anovulatory cycles, but may also be due to thyroid abnormalities, hyperprolactinemia, or polycystic ovary syndrome. Symptoms are commonly experienced during perimenopause, which substantially impacts an individual's health and daily function. Vasomotor symptoms (eg, hot flashes and night sweats) develop in up to 80% of individuals and the symptoms on average persist for 7.4 years, with longer duration in those experiencing menopause at an earlier age.[9] However, only less than one-third of individuals seek medical attention for treatment. While the frequency of vasomotor symptoms varies, individuals on average report having 4 to 5 hot flashes per day with some experiencing as many as 20 hot flashes per day. Individuals of different race/ethnicity experience vasomotor symptoms differently, whereas Black individuals had the highest prevalence and longest duration of vasomotor symptoms, followed by Hispanic and White individuals with Asian individuals having the lowest prevalence.[9] Vasomotor symptoms persist for an average of 7.4 years with moderate-to-severe vasomotor symptoms extending in 42% of individuals aged 60 to 65 years.[9,10] Research has shown that 60% of individuals experience moderate hot flashes, 20% experience severe vasomotor symptoms, 68% experience urinary incontinence, 23% experience psychological symptoms (eg, depression), and 42% to 88% experience sexual dysfunction, along with reports of increased sleep disturbances.[10–13] Genitourinary syndrome of menopause (GSM) is a collection of symptoms associated with decreased estrogen and other sex steroids that create changes to the labia, clitoris, vestibule/introitus, vagina, urethra, and bladder.[13] Resulting symptoms include genital dryness, burning, and irritation; sexual symptoms of lubrication difficulty, discomfort or pain, and impaired sexual function; and urinary urgency, dysuria, and recurrent urinary tract infections. Vaginal symptoms occur in 27% to 84% of individuals.[13] While vasomotor symptoms generally improve over time, GSM is usually progressive without effective therapy. The majority of individuals report GSM negatively affect their sexual function and overall quality of life, yet many are not aware these symptoms are related to menopause and therefore these symptoms remain untreated.[12,13]

Perimenopause is associated with a higher vulnerability to depression with the risk increasing from early-to-late perimenopause and decreasing during postmenopause.[14] During the menopausal transition or early postmenopause, individuals are two to four times more likely to experience major depressive episode than in premenopause.[10] Those who experience a major depressive episode during perimenopause often represents a reoccurrence of their major depressive disorder.[14]

In addition to the symptoms of menopause, loss of estrogen production results in significant metabolic changes including effects on body composition, cognition, lipids, vascular function, and bone metabolism. The menopause transition is associated with a significant increase in central abdominal fat leading to an average weight gain during the menopausal transition of 5 lb (2.3 kg); however, this is likely to be related to aging and lifestyle rather than menopause.[1] Skin changes including decreased thickness and elasticity, loss of collagen, and wrinkling, and hair changes including alopecia and hirsutism are also associated with menopause. Poor concentration and memory are common during the menopause transition and early postmenopause.[1] Approximately 60% of individuals report memory performance and processing speed slightly decline during the menopausal transition, characterized by the absence of learning during perimenopause that resolves in postmenopause.[15] While these cognitive symptoms can be affected by other symptoms of menopause such as sleep disturbances, hot flashes, depressed mood, fatigue, and midlife stressors, recent studies have suggested that the decline in cognitive performance is not related to menopause, but rather, is a function of chronological aging.[15]

Abnormal uterine bleeding (AUB) is characterized by a deviation of regularity, frequency, duration, or volume of menstrual fluid typical of a female's menses. In general, AUB may occur during the perimenopausal years because of anovulatory cycles; however, unusual uterine bleeding always merits investigation when it cannot be simply explained by menopausal cyclical irregularity. Hormonal treatment options for AUB include insertion of an intrauterine progestin-only device, systemic progestogen therapy, or the combined oral contraceptive pill unless contraindicated.[1]

TREATMENT

Desired Outcomes

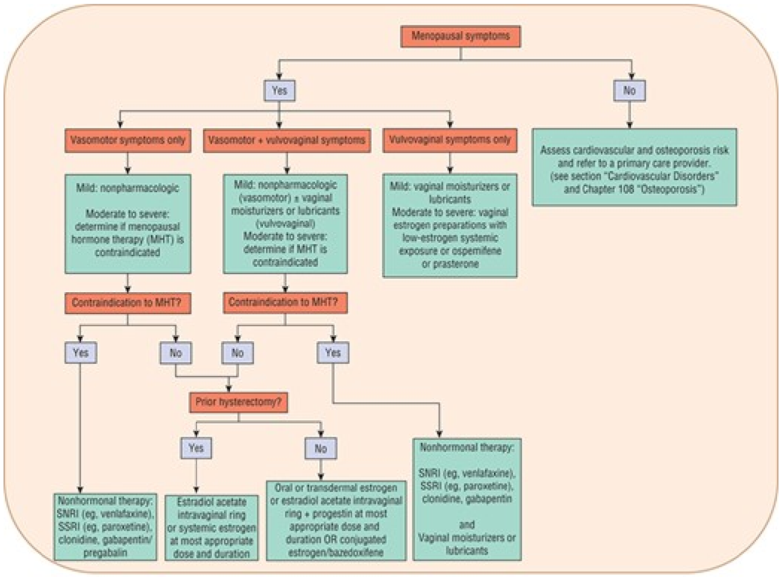
Menopause is a natural life event, not a disease. The primary goals of therapy for menopause are to relieve symptoms and improve quality of life while minimizing adverse effects. This can be best achieved by individualizing treatment based on medical, social, and family history as well as the individual's symptoms and quality of life goals.

General Approach to Treatment

In those with mild vasomotor symptoms, nonpharmacologic therapy can be considered, while menopausal hormone therapy (MHT) is the treatment of choice for individuals with moderate-to-severe hot flashes and vulvovaginal symptoms, unless contraindicated (Table 102-1). Topical vaginal products should be reserved for individuals exclusively experiencing vulvovaginal atrophy. Treatment of mild vulvovaginal symptoms should include nonhormonal lubricants and moisturizers. However, for some individuals, these treatments are not effective. Figure 102-1 outlines an algorithm for the general management of menopausal individuals.

FIGURE 102-1

Algorithm for pharmacologic management of menopausal symptoms. SNRI: serotonin norepinephrine reuptake inhibitor, SSRI: selective serotonin reuptake inhibitor.



Menopausal symptoms
Yes
No
Vasomotor symptoms only
Vasomotor + vulvovaginal symptoms
Vulvovaginal symptoms only
Assess cardiovascular and osteoporosis risk and refer to a primary care provider. (see section "Cardiovascular Disorders" and Chapter 108 "Osteoporosis")
Mild: nonpharmacologic
Moderate to severe: determine if menopausal hormone therapy (MHT) is contraindicated
Mild: nonpharmacologic (vasomotor) ± vaginal moisturizers or lubricants (vulvovaginal)
Moderate to severe: determine if MHT is contraindicated
Mild: vaginal moisturizers or lubricants
Moderate to severe: vaginal estrogen preparations with low-estrogen systemic exposure or ospemifene or prasterone
Contraindication to MHT?
Contraindication to MHT?
Yes
No
No
Yes
Prior hysterectomy?
Yes
No
Nonhormonal therapy: SNRI (eg, venlafaxine), SSRI (eg, paroxetine), clonidine, gabapentin/pregabalin
Estradiol acetate intravaginal ring or systemic estrogen at most appropriate dose and duration
Oral or transdermal estrogen or estradiol acetate intravaginal ring + progestin at most appropriate dose and duration OR conjugated estrogen/bazedoxifene
Nonhormonal therapy:
SNRI (eg, venlafaxine), SSRI (eg, paroxetine), clonidine, gabapentin
and
Vaginal moisturizers or lubricants

TABLE 102-1

FDA-Labeled Indications and Contraindications for Menopausal Hormone Therapy with Estrogens and Progestins

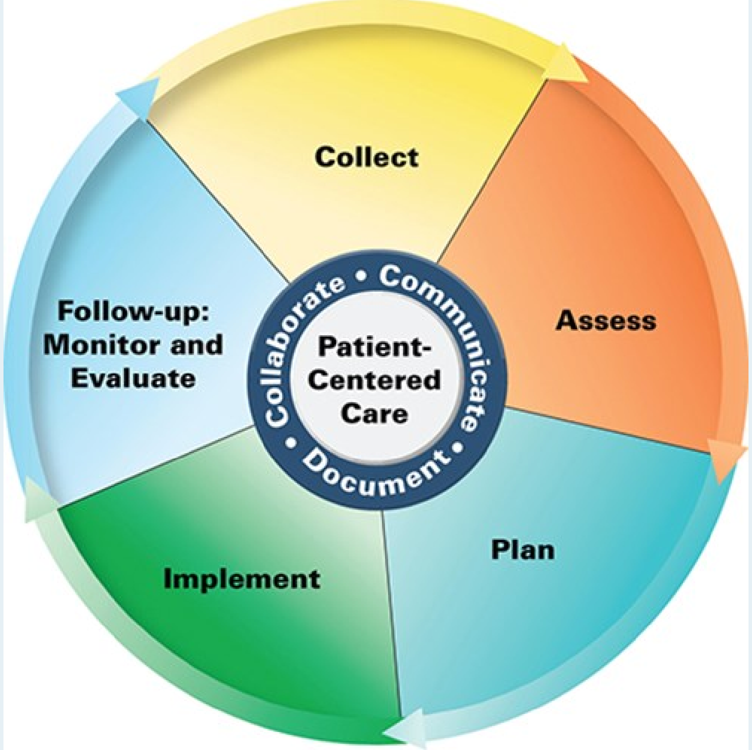
Indications	
For systemic use	Treatment of moderate-to-severe vasomotor symptoms (ie, moderate-to-severe hot flashes)
For intravaginal use (low systemic exposure)	Treatment of moderate-to-severe symptoms of genitourinary syndrome of menopause (ie, moderate-to-severe vaginal dryness, dyspareunia, and atrophic vaginitis)
Contraindications	
Absolute contraindications	Undiagnosed abnormal genital bleeding Known, suspected, or history of cancer of the breast Known or suspected estrogen- or progesterone-dependent neoplasia Active deep vein thrombosis, pulmonary embolism, or a history of these conditions Active or recent (eg, within the past year) arterial thromboembolic disease (eg, stroke, myocardial infarction) Liver dysfunction or disease
Relative contraindications	Elevated blood pressure Hypertriglyceridemia Impaired liver function and past history of cholestatic jaundice Hypothyroidism Fluid retention Severe hypocalcemia Ovarian cancer Exacerbation of endometriosis Exacerbation of asthma, diabetes mellitus, migraine, systemic lupus erythematosus, epilepsy, porphyria, and hepatic hemangioma

① The decision to use MHT and the type of formulation used must be individualized based on several factors, including personal preference, age, menopause onset, the severity of menopausal symptoms and the risks of cardiovascular disease, breast cancer, osteoporotic fracture, and venous thromboembolic events (VTE). Breast cancer risk is increased with concomitant progestogen use in menopausal individuals with an intact uterus, and VTE may also increase with higher estrogen doses and oral administration.[16]

The duration of therapy also needs to be individualized according to the severity of symptoms, health status, and concerns regarding risks. Approved indications of MHT include treatment of moderate-to-severe vasomotor symptoms, moderate-to-severe vulvovaginal atrophy, and prevention of postmenopausal osteoporosis. For treatment of vasomotor symptoms, systemic MHT is the most effective pharmacologic intervention (Fig. 102-1). For genitourinary syndrome of menopause, such as vaginal dryness, intravaginal products should be considered.[6,13]

PATIENT CARE PROCESS

Patient Care Process for Post Menopausal Hormone Therapy



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics: age, race, cis or transgender
- Personal and family medical history: cancer, cardiovascular disease, thromboembolic risks, osteoporosis, date of last menses, menstrual bleeding pattern, diabetes (Table 102-1)
- Gynecological surgical history
- Physical examination: breast and pelvic examination, Papanicolaou (PAP) cervical cytologic examination, mammography, liver function, assessment for gallbladder disease
- Bone mineral density results
- Current medication including prescription, nonprescriptions, and dietary supplements
- Social history: Tobacco use, ethanol use, caffeine use
- Symptoms: hot flashes, night sweats, irregular periods, sleep disturbances, mood changes, thinning of hair, difficulty with concentration or memory, arthralgia, and genitourinary syndrome of menopause (eg, vaginal dryness, burning and irritation of reproductive organs and structures, sexual dysfunction, dysuria, dyspareunia, urinary urgency, recurrent urinary tract infections) (see Clinical Presentation box)
- Signs: Abnormal uterine bleeding, decreased vaginal moisture, vaginal tissue fragility, thinning hair, skin changes (see Clinical Presentation box)
- Labs/Tests: Thyroid function tests, iron stores, serum prolactin, lipid profile, follicle stimulating hormone (FSH) levels
- Patient's expectations, preferences, and goals for therapy (eg, reduce frequency/predictability of menses, symptom relief)

Assess

- Evaluate the individual's menstrual cycle history or menstrual calendar

- Stage of menopausal transition; perimenopause, menopause, postmenopause
- Does patient still have a uterus intact
- Rule out causes other than the menopausal transition for abnormal uterine bleeding and amenorrhea (eg, pregnancy, hyperprolactinemia, and hyperthyroidism) (see Clinical Presentation box)
- Emotional status (eg, anxiety, depression) (see Clinical Presentation box)
- Define patient's risk for osteoporosis, coronary heart disease, thromboembolic risks, cancer
- Risks and benefits of various therapy options (Table 102-3)
- Insurance coverage and patient's ability to afford treatment options

Plan*

- Nonpharmacologic lifestyle interventions including smoking cessation, dress in layers, weight loss, exercise, limit intake of spicy foods, caffeine, and hot beverages
- Develop a drug therapy regimen (including specific medication, dose, route, frequency, duration) to provide symptom relief, maximize adherence, provide endometrial protection, and minimize long-term risk (Tables 102-3 through 98-7, Table 102-9, and Fig. 102-1)
- Monitoring parameters for efficacy of therapy: reduction in vasomotor symptoms, improvement in genitourinary syndrome of menopause (GSM) signs and symptoms, mood stability, improved sleep (Table 102-8)
- Monitoring parameters for adverse effects: breast tenderness, bloating, premenstrual-like symptoms, mood changes, withdrawal bleeding or abnormal bleeding patterns (Table 102-8)
- Self-monitoring for vasomotor symptoms, GSM signs and symptoms, adverse effects, signs and symptoms of thrombosis

Implement*

- Provide patient education regarding all elements of treatment plan
- Educate patient regarding risks and benefits of treatment options, lifestyle modifications, drug-specific information
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Resolution of bothersome symptoms
- Presence of adverse effects
- Patient adherence to treatment
- Reevaluate need and continuation of therapy (Table 102-8)

**Collaborate with patient, caregivers, and other healthcare professionals.*

Nonpharmacologic Therapy

Mild menopausal symptoms may be managed effectively with lifestyle modifications, including wearing layered clothing that can be removed or added as necessary, lowering room temperature, decreasing intake of hot spicy foods, caffeine, and hot beverages, exercise, and other general good health practices. Some dietary supplements have been promoted as alternatives to MHT with conflicting results.[17]

Pharmacologic Therapy

Pharmacologic therapy is the mainstay of management of menopausal symptoms and includes both hormonal (estrogen with or without progestogen) and nonhormonal medications.

Drug Treatment of First Choice

② Menopausal hormone therapy is the most effective treatment option for alleviating moderate-to-severe vasomotor symptoms. In individuals with an intact uterus, systemic MHT consists of an estrogen plus a progestogen or a tissue-selective estrogen complex (estrogen/bazedoxifene) to prevent endometrial hyperplasia. In those who have undergone hysterectomy, estrogen therapy is given unopposed by a progestogen (ie, as monotherapy). Mild vulvovaginal symptoms may be adequately managed with nonhormonal lubricants and moisturizers.[13] However, vaginal estrogen therapy (cream, tablet, and ring) may be needed for moderate-to-severe vulvovaginal symptoms. Progestogen therapy for endometrial protection is not recommended with the use of low-dose vaginal estrogens (ie, those with minimal systemic exposure) with the exception of one vaginal ring (Femring®) known to deliver adequate systemic estrogen concentration to treat vasomotor symptoms.[13,18]

A number of national and international guidelines and consensus statements on the management of menopause are available.[6,7,13,17,19–27] The US Preventive Services Task Force also provides a recommendation statement on the use of MHT for the prevention of chronic medical conditions in postmenopausal individuals.[28]

Therapy for Perimenopausal Individuals

Despite a decline in fertility with age, sexually active females may become pregnant during the perimenopausal years. Furthermore, perimenopausal individuals can experience hot flashes despite having menstrual cycles. Combined hormonal contraceptives (containing low-dose estrogen and progestogen) provide contraception and vasomotor symptom relief. Perimenopausal individuals should not use estrogen-containing contraceptives if they smoke or have a history of estrogen-dependent cancer, cardiovascular or cerebrovascular disease, hypertension, diabetes with vascular disease, or risk factors for thromboembolism, liver disease, or migraine headaches. For perimenopausal individuals with AUB due to anovulatory cycles, a progestin-only intrauterine device may be a useful option. Combined hormonal contraceptives provide the additional benefit of reducing the risk of ovarian and endometrial cancer.

Menopausal Hormone Therapy for Vasomotor and Genitourinary Syndrome Symptoms

Menopausal hormone therapy remains the most effective treatment for moderate and severe vasomotor symptoms, impaired sleep quality, and vulvovaginal symptoms of menopause.[1,6,13,20–22]

Vasomotor Symptoms

Fewer than 25% of females experience a menopausal transition without symptoms, whereas more than 25% suffer severe menopausal symptoms, most commonly hot flashes and night sweats. The average duration of vasomotor symptoms is 7.4 years with some individuals experiencing symptoms for more than 10 years. Individuals with mild vasomotor symptoms can experience relief by lifestyle modification, and at least 25% of participants of clinical trials reported significant improvement of vasomotor symptoms when taking placebo. The most effective treatment for vasomotor symptoms is MHT.[1,6,20–22] Benefits and risks of MHT should be weighed individually and assessed on an annual basis. Clinicians should select the most appropriate dose, duration, and routes of administration based on patient symptoms and medical history to provide the most benefits.

Genitourinary Syndrome of Menopause

The lower genitourinary tract contains a high concentration of estrogen receptors and is particularly vulnerable to estrogen deficiency, resulting in symptoms which progressively worsen over time. Up to 85% of postmenopausal individuals report symptoms of GSM,[13] which results in vaginal dryness, burning, irritation, discomfort, and dyspareunia. Lower urinary tract symptoms include urethritis, recurrent urinary tract infection, urinary urgency, and frequency.

Most individuals with moderate-to-severe vulvovaginal symptoms require local or systemic estrogen therapy for symptom relief. Local (vaginal) estrogen delivery is preferred when vaginal symptoms are the only menopausal symptom complaint, as it minimizes systemic absorption and is more effective than oral estrogen therapy.[6,13] Vaginal estrogen has also been shown to improve atrophic symptoms and vaginal mucosal appearance, decrease vaginal pH, improve vaginal and/or urethral cytology, and reduce the risk of lower urinary tract symptoms and recurrent urinary tract infections possibly by modifying the vaginal flora.[6,13] Local estrogen therapy, but not systemic estrogen treatment, has demonstrated robust evidence for treatment of urinary incontinence in postmenopausal individuals.[29] Moderate-to-severe vulvovaginal symptoms can be treated with a vaginal estrogen cream, tablet, or ring; or with the selective estrogen receptor modulator (SERM) ospemifene given 60 mg orally per day.[13] Current data do support benefit of using combined systemic and vaginal estrogen in individuals suffering from severe GSM.[13] Ospemifene carries similar prescribing precautions as those with estrogens and other estrogen antagonist/antagonists, including increased risk of endometrial cancer. It also has a nearly full estrogen agonist effect in the vaginal epithelium to improve dyspareunia, sexual function, and overall satisfaction in postmenopausal individuals with moderate-to-severe vaginal dryness and has been well tolerated.[13] Individuals with moderate-to-severe dyspareunia can also consider prescription intravaginal dehydroepiandrosterone (DHEA) prasterone.

Dose-related adverse effects of vaginal estrogen include vaginal discharge, vulvovaginal candidiasis, vaginal bleeding, breast pain, and nausea.[13] Current prescribing information for low-dose vaginal estrogen therapy contains precautions similar to systemic hormone therapy (eg, CHD, stroke, VTE, breast, and endometrial cancer); however, these risks are highly unlikely given the minimal systemic absorption and reassuring findings from clinical and observational studies.[13] Concomitant progestogen therapy is unnecessary when low-dose vaginal estrogen is used with the exception of one vaginal ring (Femring) which is known to deliver a systemic concentration of estrogen.[18] Therapeutic response to vaginal estrogen therapy is typically attained after 2 weeks of daily estrogen use. For maintenance therapy, the frequency of administration is generally decreased to two to three times weekly.

Vaginal rejuvenation devices using carbon dioxide laser therapy and other energy-based devices to destroy or reshape vagal tissues marketed to help individuals with variety of symptoms related to menopause such as urinary incontinence, vaginal atrophy, dyspareunia, itchiness, or sexual dysfunction. They are considred a new approach and their use have increased globally despite recent warning posed by the US FDA due to reports of serious risks.[30] Efficacy and long-term safety of these procedures have not yet established and international societies do not endorse its use.[31] Further well-designed clinical trials are needed before definite conclusions can be drawn. Use of only FDA-approved therapies is recommended for individuals suffering from GSM.

Assessing Benefits and Risks of Systemic Menopausal Hormone Therapy

The Women's Health Initiative (WHI) was a randomized, double-blind, placebo-controlled trial launched in 1991 to evaluate the effects of MHT on heart disease, osteoporosis, and cancer. The WHI trial had two arms: the estrogen-plus-progestin arm involving females with an intact uterus and the estrogen-alone arm involving females with a history of hysterectomy.[16] The combined estrogen and progestin arm included 16,608 participants aged 50 to 79 years (mean age, 63 years), and the estrogen-only arm enrolled 10,739 participants aged 50 to 79 years (mean age, 64 years). The primary outcome was incidence of coronary heart disease (CHD) (nonfatal myocardial infarction or CHD death), and the primary safety outcome was invasive breast cancer. A global index was used to summarize the balance of risks and benefits, which included the two primary outcomes plus stroke, pulmonary embolism, endometrial cancer, colorectal cancer, hip fracture, and death due to other causes. The estrogen-plus-progestin arm was terminated prematurely after only 5.2 years (the planned duration was 8.5 years) because the global index statistic supported risks exceeding benefits on the major clinical outcomes. The estrogen-only arm also was terminated early (after 6.8 years) because of excess risk of stroke. Results of the WHI trial are shown in Table 102-2.[16] Upon discontinuation of the trial, participants were asked to discontinue study medication and invited to participate in a follow-up phase of the study that has resulted in multiple ancillary analyses.[14,16,32–38]

TABLE 102-2

Principal Results of the Women's Health Initiative Hormone Therapy Trial

	Estrogen + Progestogen Arm (Median Duration 5.6 years)			Estrogen-Only Arm (Median Duration 7.2 years)		
Outcome	MHT (*n* = 8,506)	Placebo (*n* = 8,102)	Hazard Ratio (Nominal 95% CI)	MHT (*n* = 5,310)	Placebo (*n* = 5,429)	Hazard Ratio (Nominal 95% CI)

CI, confidence interval; MHT, menopausal hormone therapy.

Data from Ref. 16.

Use of MHT has greatly evolved to recognize the need to tailor therapy for individuals based on patient-specific factors (eg, age, risk factors, and goals of therapy). A summary of various clinical considerations described in the 2017 Hormone Therapy Position Statement of the North American Menopause Society is provided in Table 102-3.[1,6,12,17,22,23,28,29]

TABLE 102-3

Summary of North American Menopause Society Position Statement on Menopausal Hormone Therapy

Symptom/Condition	Summary Statement(s)
Vasomotor symptoms	Estrogen therapy (± progestogen) is the most effective therapy, including consequences of vasomotor symptoms such as sleep quality, irritability, difficulty concentrating, and quality of life
Genitourinary syndrome of menopause (GSM)	Estrogen therapy is the most effective treatment for moderate-to-severe GSM symptoms. Local therapy is recommended for sole vaginal symptoms; progestogen generally not indicated for low-dose vaginal estrogen therapy. Individuals at risk of endometrial cancer may warrant endometrial surveillance. No data to support initial use of combined systemic and vaginal estrogen for severe GSM.
Sexual function	Low-dose local estrogen therapy may improve lubrication, blood flow, and vaginal sensation; however, MHT is not recommended as treatment for other problems of sexual function (eg, libido, orgasmic response)
Osteoporosis	Standard-dose MHT reduces postmenopausal osteoporotic fractures (hip, vertebral, and nonvertebral) and many systemic MHT products are approved for prevention of osteoporosis. MHT is not indicated for treatment. Benefits of MHT dissipate when discontinued
Coronary heart disease	Observational and randomized control data are conflicting. Estrogen only therapy may reduce CHD risk when initiated in newly menopausal Individuals (age 50-59 years). Estrogen + progestogen therapy initiated between ages 50 and 59 years or within 10 years of menopause does not increase CHD risk. Individuals initiating therapy after 10 years since menopause have an increased risk of CHD. MHT is not recommended any time for coronary protection
Stroke	Increased risk of ischemic stroke (not hemorrhagic) exists with estrogen only and estrogen + progestogen use.
Venous thromboembolism (VTE)	Increased risk of VTE with oral MHT across all ages. Risk increases with personal risk factors including obesity, previous history of VTE,and the presence of Factor V Leiden mutation. The type of progestogen may impact risk. Transdermal formulations have lower VTE risk than oral formulations

CHD, coronary heart disease; MHT, menopausal hormone therapy; VTE, venous thromboembolism.

Data from Refs. 1, 6, 12, 16, 19, and 23.

Furthermore, several national and international organizations have published guidelines or position statements to outline points of consensus regarding the safe and effective use of MHT.[1,6,17,19,20,23–27,39]

Overall, consensus recommendations regarding the use of MHT include:

- Menopausal hormone therapy is the most effective treatment for vasomotor symptoms. Healthy, recently menopausal individuals (before the age of 60 years or within 10 years of menopause) have the most favorable benefit-to-risk profile.
- Menopause hormone therapy should not be used for the primary and secondary prevention of CHD at present.
- Estrogen-only therapy may decrease heart disease and all-cause mortality in 50- to 59-year-old individuals with a history of hysterectomy. In this age group, combined estrogen and progestogen therapy shows similar trends for mortality, but no significant difference in CHD.
- Estrogen alone is appropriate for individuals after hysterectomy; additional progestogen is required when a uterus is present.
- Use of MHT should be individualized based on the severity of menopausal symptoms and personal risk factors (eg, age, time since menopause,

history of VTE, stroke, ischemic heart disease, osteoporosis risks, and breast cancer).

- Risk of VTE and stroke increases with oral MHT containing estrogen, but the absolute risk is low in individuals below 60 years of age. Based on observational studies, transdermal MHT and low-dose oral estrogen therapy have a lower risk of VTE and stroke compared to standard-dose oral estrogen regimens.
- Menopausal hormone therapy is contraindicated in individuals with a personal history of breast cancer. The risk of MHT-related breast cancer is associated with the addition of progestogen to estrogen and increases after 5 or more years of continuous combined use. However, the use of estrogen alone decreases rather than increase breast cancer risk.
- Select the most appropriate dose, duration, and routes of administration of hormone therapy to provide the most benefits and adequately manage menopausal symptoms. Duration of therapy should not be discontinued solely based on the patient's age.

Cardiovascular Disease

③ Cardiovascular disease—including coronary artery disease, stroke, and peripheral vascular disease—is the leading cause of death among females, but MHT should not be used for reducing the risk of cardiovascular disease. Menopause is associated with the development of a more adverse lipid profile, and the presence of vasomotor symptoms has been associated with an increased risk of cardiovascular disease.[40]

In the decade prior to the publication of the WHI results in 2002, an expectation of coronary benefit had been a major reason for use of postmenopausal hormones because observational studies indicated that individuals who use MHT have a 35% to 50% lower risk of CHD than nonusers. In addition, previous studies had shown that estrogen exerts protective effects on the cardiovascular system, including lipid-lowering, antioxidant, and vasodilating effects.[41] However, in the 2000s, published results of several randomized clinical trials provided no evidence of cardiovascular disease protection and even some evidence of harm with MHT.[16,34]

The primary findings of the estrogen plus progestogen arm of the WHI trial showed an overall increase in the risk of CHD (HR 1.18, 95% CI 0.95-1.45) among healthy postmenopausal participants receiving combined estrogen–progestogen MHT compared with those receiving placebo.[16] The primary findings of the estrogen-only arm of the WHI trial show no effect (either increase or decrease) on the risk of CHD in participants taking estrogen alone.[16] Similar patterns of risk and benefits profile of estrogen-alone therapy are seen in individuals with and without bilateral oophorectomy.[6,16] In the extended post-intervention follow-up of 13 years revealed that individuals who initiated MHT 10 or more years after the time of menopause tended to have increased CHD risk compared with those who initiated therapy within 10 years of menopause.[14] Estrogen plus progestogen was associated with a non-significantly elevated CHD events in individuals aged 50 to 59 years, whereas estrogen alone was associated with reduced risk of CHD in those who were younger than 60 years and/or who are within 10 years of menopause onset.[6,16] Older individuals (age 70-79) who are more than 20 years past menopause onset experience highest risk of CHD that is significant compared with placebo group when estrogen plus progestogen therapy is initiated.[6,16] Most individuals who commence estrogen or estrogen plus progestogen therapy do so within the first few years of becoming menopausal.

A randomized controlled study of 1,006 recently menopausal individuals revealed that 10-year MHT was associated with a significantly reduced risk of cardiovascular disease.[42] In addition, studies of recently menopausal individuals showed that the presence and severity of hot flashes are associated with vascular endothelial dysfunction and vascular inflammation (markers of increased risk for CHD); MHT improved both these parameters.[43]

In an attempt to resolve some of the controversies, the Kronos Early Estrogen Prevention Study (KEEPS) randomized 727 recently menopausal participants (mean age 52 years and less than 3 years since FMP) to cyclic progestogen and either oral estrogen (conjugated estrogen 0.45 mg/day), transdermal estrogen (estradiol 50 μg/day), or placebo to examine the rate of atherosclerosis.[43] While KEEPS provided reassurance regarding safety and efficacy of MHT regimen, there was no difference among the study arms on atherosclerotic progression as evidenced by carotid intima-media thickness (CIMT) and coronary artery calcium during 4 years of treatment.[43] However, in the Early versus Late Intervention Trial with Estradiol (ELITE) trial, use of hormone therapy (oral 17β-estradiol 1 mg/day plus progesterone vaginal gel administered sequentially in participants with intact uterus) showed reduced carotid intima-media thickness progression in early postmenopausal individuals who initiated hormone therapy within 6 years of menopause onset, but similar cardioprotective effect was not observed among postmenopausal individuals who initiated hormone therapy 10 years after menopause onset.[44] Posttrial analysis from ELITE further supported that higher plasma estradiol (E2) levels were differentially associated with atherosclerosis progression according to the timing of hormone therapy initiation.[45] While both groups have higher plasma estradiol levels, those in early postmenopause had decreased CIMT progression rate where as individuals in late postmenopause had increased CIMT progression rate. While results from the ELITE trial provide preliminary evidence for the "timing hypothesis" or the "window of opportunity" concept that the benefits of hormone therapy are dependent on the timing of initiation and that hormone therapy may be cardioprotective if started around the time of menopause. Therapy may be harmful when initiated in late postmenopausal Individuals, and currently available clinical data remain inconsistent and additional research is still needed.[1,46]

With available data, current guidelines caution against initiating or continuing menopausal hormone therapy solely for primary or secondary prevention of cardiovascular disease.[6,28] Use of menopausal hormone therapy is not indicated for individuals with a high risk of CVD.[6] Adherence to a healthful lifestyle (smoking cessation, regular exercise, healthy diet, and body mass index less than 25 kg/m^2) may prevent the onset of cardiovascular disease in postmenopausal individuals.[17] It should be noted that use of vaginal estrogen is not associated with an increased risk of CHD.[32]

Oral estrogen monotherapy have favorable effect on lipoprotein levels, glycemia, insulin, and CVD risks; however, addition of progestogen attenuates some of the beneficial effects of estrogen.[47] In the estrogen plus progestogen arm of the WHI study, the increased risk for stroke (HR 1.37, 95% CI 1.07-1.76) and pulmonary embolism (HR 1.98, 95% CI 1.36-2.87) was evident, even during the postintervention phase.[16] Increased risk was observed only for ischemic stroke but not for hemorrhagic stroke. In the estrogen-alone arm of the study, a similar increased risk (HR 1.35, 95% CI 1.07-1.70) for stroke was observed.[16] After the cessation of treatment, the risks for stroke remain higher compared with placebo groups at 13-year follow-up.[16] The optimal duration of hormone therapy with respect to stroke risk remains to be determined.[48] Oral micronized progesterone seems to have least adverse effects.[49] Transdermal estrogen (< 50 µg/day) have improved adverse effect profile than oral estrogens and suggested a lower risk of stroke than oral estrogens.[47,48] It should be noted that use of vaginal estrogen is not associated with an increased risk of stroke.[32]

In the cumulative 18-year follow-up from WHI trials, hormone therapy with combined estrogen–progestogen or estrogen alone have not been shown to increase all-cause mortality including death from CVD, CHD, and stroke.[33] In fact, younger individuals (aged 50-59 years) who initiated estrogen monotherapy for 7.1 years was found to have a significant and sustained beneficial impact on overall mortality.[33] Recent meta-analysis of randomized controlled trials and observation studies support similar findings that menopausal hormone therapy was not associated with increase all-cause death, myocardial infarction, or cardiovascular death but was associated with an increased risk of stroke, venous thromboembolism, and pulmonary embolism which further emphasized that underlying disease and timing of initiation should be carefully considered before starting MHT.[49]

The Endocrine Society clinical practice guideline recommends evaluating an individual's 10-year CVD risk before initiation of MHT using the ACC/AHA Cardiovascular Risk Calculator.[20,50] Regardless of years since menopause onset, the guideline recommends avoiding hormone therapy for symptomatic individuals at high CV risk (>10%) and advocates for the use of nonhormone therapy. For individuals at moderate risk of CVD (5%-10%), use of transdermal estrogen is preferred over oral formulations with oral micronized progesterone in those with an intact uterus.[20]

Venous Thromboembolism

In general, VTE, including thrombosis of the deep veins of the legs and embolism to the pulmonary arteries, is uncommon in the general population. Conversely, individuals taking oral estrogen therapy have a twofold increased risk for thromboembolic events, with the highest risk occurring in the first 1 to 2 years of use.[6,16,34] One of the main predictors of future VTE is duration of hormone therapy use.[48] However, individuals with certain risk factors for VTE including those with a Factor V Leiden mutation, protein C and protein S deficiencies, congenital thrombophilic disorders, obesity, and history of previous thromboembolic events are at increased risk with MHT.[6,51] Patient with confirmed COVID-19 infections are also at higher thromboembolic risk and may warrant special management and considerations.[52] Lower doses of estrogen are associated with a decreased risk for thromboembolism as compared with higher doses. Oral administration of estrogen increases the risk of VTE compared to the transdermal route.[6,47,51] There is no indication for thrombophilia screening before initiating MHT. However, MHT should be avoided in individuals at high risk for thromboembolic events.

It should be noted that use of vaginal estrogen is not associated with an increased risk of pulmonary embolism or VTE.[32]

Breast Cancer

④There have been controversies regarding the association between MHT and breast cancer. The risk of breast cancer associated with MHT is associated with the addition of progestogen therapy to estrogen, as use of estrogen alone does not increase the risk of breast cancer. The WHI trial found that combined estrogen plus progestogen oral therapy has an increased risk of invasive breast cancer (HR 1.28, 95% CI: 1.13-1.45) and a trend toward increasing risk with increasing duration of therapy.[36] After discontinuation of estrogen plus progestogen therapy, WHI study results demonstrated a year-to-year reduction in breast cancer risk but elevated risk persists more than a decade after discontinuation of hormone therapy (HR 1.23, 95% CI: 0.96-1.59).[36] On the contrary, the estrogen-only arm of the WHI trial found a lower risk for breast cancer (HR 0.78, 95% CI: 0.65-0.93) after more than 20 years of cumulative follow-up, which persisted after treatment discontinuation.[36] This association between estrogen-only therapy and lower incidence of breast cancer was evident in year 5 and subsequently thereafter, the observed benefit was greater among participants without first-degree relative with breast cancer.[36] Furthermore, death from breast cancer was significantly lowered among postmenopausal participants who took estrogen monotherapy compared to placebo (HR 0.60, 95% CI: 0.37-0.97).[35] No significant differences by age, year since menopause, duration of prior hormone use, or gap time (time since menopause to earlier of first hormone therapy use) was observed in regards to breast cancer risks among postmenopausal individuals on hormone treatments.[35] However, younger postmenopausal individuals (aged 50-59 years) who have some years of estrogen deprivation (> 5 years) prior to starting hormone therapy have the most favorable health benefits versus risks profile. This is especially evident for breast cancer, whereas post-hysterectomy individuals (aged 50-59 years) having short gap times (< 5 years) prior to starting hormone therapy do not show breast cancer risk reduction.[53] Further analysis suggested for younger individuals (aged 50-59 years), that lower breast cancer risk with estrogen-alone therapy, are more closely tied to a large gap time than to prior bilateral oophorectomy status.[54] The benefit of large gap time could possibly be supported by the estrogen-induced apoptosis theory, which suggested that prolonged periods of estrogen deprivation cause breast cancer cells to become vulnerable and undergo apoptotic cell death when exposed to exogenous estrogen.[55,56] Breast cancer risk is similar between low-dose (<0.625 mg) and conventional dose (0.625 mg) of conjugated equine estrogen but a lower risk of breast cancer is noted with the transdermal formulation.[36]

Addition of progestogens to estrogen may increase breast cancer risk beyond that observed with estrogen alone.[16,17,36] In the estrogen plus progestogen arm of the WHI, the increased breast cancer risk became significant in year 6 and remained significantly thereafter.[36] The breast cancers diagnosed in females in the menopausal hormone therapy group were more likely to be in an advanced stage with lymph node involvement compared with those in the placebo group.[36] Despite increased incidence of breast cancer risk with combined estrogen plus progestogen therapy, no significant increased risk of death from breast cancer was noted during the 20 years of cumulative follow-up (HR 1.35, 95% CI: 0.95-1.95).[36] In fact, a large population-based study found that individuals who received menopausal hormone therapy prior to diagnosis of breast cancer were associated with an improved breast cancer survival with 23% to 43% risk reduction of all-cause, breast cancer and CVD mortality after approximately 18 years of follow-up.[57,58]

While estrogen plus progestogen findings from randomized controlled trials are generally consistent with the observational studies, the findings of estrogen monotherapy on incidence of breast cancer and breast cancer mortality contrast with most prospective observational studies. In a meta-analysis from the Collaborative Group on Hormonal Factors in Breast Cancer, gathered evidence from worldwide epidemiological studies, suggested that both hormone therapy regimens (estrogen plus progesterone and estrogen-only) increased incidences of breast cancer.[59] These results are also consistent with increased 20-year breast cancer mortality observed with both menopausal hormone preparations from the Million Women Study.[60] The effect of menopausal hormone therapy on breast cancer remains unsettled with discordance from observational studies and WHI studies despite several proposed explanations attempt to reconcile these discrepancies. The effect of hormone therapy on breast cancer and replications of the findings from WHI studies are needed.

For females in the United States, the lifetime risk of developing breast cancer is approximately one in eight, and the greatest incidence occurs in those older than 60 years.[61] The Endocrine Society clinical practice guideline recommends evaluating breast cancer risk before MHT initiation using either the 5-year risk assessment tool from National Cancer Institute Breast Cancer Risk Assessment Tool (https://bcrisktool.cancer.gov) or the 10-year International Breast Intervention Study calculator (http://ibis.ikonopedia.com).[20] Consideration of individual's underlying breast cancer risk should also be clearly communicated. In general, current guideline cautions against using hormone therapy for individuals in the intermediate-risk category, and advises against using systemic hormone therapy for those in the high-risk category, particularly with a personal history of breast cancer.[6,20] Hormone therapy regimens and formulations differ substantially on their effect on breast cancer risks with continuous combined estrogen-progestogen regimen associated with a three-fold increase in breast cancer risks and sequential therapy was only associated with suggestive risk.[62] Furthermore, breast cancer risk varies with the type of progestins used with dydrogesterone (not currently available in the United States) conveying a lower risk than medroxyprogesterone, levonorgesterel, and norethisterone-containing hormone regimens and increase risk with increased duration of use.[63] While use of vaginal estrogen with minimal systemic absorption has not been demonstrated to increase risk of breast cancer, use of low-dose local vaginal estrogen may be considered only after unsuccessful trials of nonhormone therapies in conjunction with consultation with the patient's oncologist.[13]

Endometrial Cancer

It is well documented that systemic estrogen alone given to individuals with an intact uterus significantly increases uterine cancer risk.[6,34,58,64] The excess risk increases with dose and duration of estrogen and persists for many years after estrogen replacement is discontinued.[6,20] While estrogen alone is appropriate for individuals after hysterectomy; use of systemic estrogen in patients with an intact uterus must always be accompanied by adequate dose and duration of progestogen for endometrial protection. The protective effect of hormone therapy on the uterus and risk of developing endometrial cancer vary based on the different types and duration of progestogen used.[64] Although results from the WHI trial's postintervention and follow-up phase demonstrated a reduced risk of endometrial cancer with combined oral MHT,[14] for symptomatic individuals with advanced cancer or higher risk for endometrial cancer, use of nonhormone therapies is still recommended and the use of systemic hormone therapy is not recommended.[64] Individuals preferring not to take progestogen may consider tissue-selective estrogen complex (estrogen/bazedoxifene) as an alternative to reduce risk of endometrial hyperplasia. Recent meta-analysis suggested that use of combined estrogen-progestogen therapy and the cyclic regimen do not increase incidence of endometrial cancer reoccurrence in postmenopausal individuals treated with early stages of endometrial cancer, but racial disparities exist on cancer reoccurrence with a much higher risk observed among Black American females.[65] In the presence of insufficient high-quality evidence, further studies are still needed to clarify the long-term impact of hormone therapy in endometrial cancer survivors.[66]

Ovarian Cancer

Lifetime risk of ovarian cancer is low (1.7%) and results from the WHI trial suggested that orally administered combined MHT does not increase the risk of ovarian cancer (HR 1.41, 95% CI: 0.75-2.66) with the risk remaining non-significant after 13 years of cumulative follow-up.[6] However, limited observation data have reported inconsistent results.[6] A meta-analysis of 37 observational epidemiological studies suggested that ovarian cancer risks is increased (RR 1.16, 95% CI: 1.06-1.26) in those who received both estrogen monotherapy and estrogen–progestogen therapy.[58] Despite the increased incidences of ovarian cancers with use of menopausal hormone therapy, individuals who received menopausal hormone therapy (either estrogen-only or estrogen–progestogen therapy) prior to diagnosis of ovarian cancer, had improved ovarian cancer overall survival.[58,67]

Ultimately, the use of hormone therapy in menopausal ovarian cancer survivors need to be individualized because ovarian cancers have different histological subtypes and require different considerations balancing the risks of cancer reoccurrence and quality of life is needed.[68] Although the evidence is limited, hormone therapy for ovarian cancer survivor with germ cell tumor or non-serous epithelial ovarian cancer is generally considered safe.[66,68] However, the use of systemic or topical hormone therapy are not recommended for patients with history of ovarian granulosa cell tumor as this cancer subtype is hormonally active and their use warrant careful consideration. Patients should always involve their treating oncologist in decision making regarding the use of hormone therapy. Further data are needed for more rare ovarian tumors such as borderline tumors and sex-cord stromal tumors.[68]

Lung Cancer

Estrogen and progesterone receptors are expressed in lung cancer cells. The WHI trial found that combined oral estrogen–progestogen therapy did not increase lung cancer incidence,[16] but significantly increased deaths from lung cancer have been observed in the post hoc analysis of the WHI intervention, mainly from non-small cell lung cancers in individuals already at elevated risk due to past or current smoking status.[69] The increased risk of lung cancer mortality (RR 1.10, 95% CI: 1.00-1.21) was noted in a recent meta-analysis of three randomized controlled trials in patients who received estrogen–progestogen therapy.[58] In the estrogen-only arm of the WHI trial found no increased risk for lung cancer; however, it should be noted that the WHI was not originally designed to assess the relationship between hormone use and lung cancer.[6] Further studies to explicitly evaluate association between hormone therapy use and lung cancer mortality are warranted.

Osteoporosis

Postmenopausal osteoporosis is a serious age-related condition that affects millions of females throughout the world. Menopause is accompanied by accelerated bone loss, and the central role of estrogen deficiency in postmenopausal osteoporosis is well established. The WHI was the first randomized trial to demonstrate that MHT reduces the risk of fractures at the hip, spine, and wrist.[6] Estrogen therapy reduces bone turnover and increases bone density in postmenopausal individuals of all ages. In the WHI, both oral estrogen monotherapy and estrogen-progestogen reduced vertebral, hip, and other fractures. The protective effect persists as long as the treatment is maintained; however, bone protection is quickly lost with cessation of therapy, although there is no evidence of rebound fracture.[6,16] Several oral and transdermal estrogen only and estrogen-progestin combination formulations, as well as the estrogen-bazedoxifene product, are FDA-approved for the prevention of postmenopausal osteoporosis. The standard bone-sparing daily estrogen dose is equivalent to 0.625-mg conjugated equine estrogen (CEE) with lower effect on bone mineral density with lower doses.

In individuals who experience vasomotor symptoms and are younger than 60 years of age or within 10 years of menopause onset, systemic estrogen therapy may be indicated for the prevention of bone loss and osteoporotic fractures.[6] General protective health measures, such as regular weight-bearing exercise and avoidance of detrimental lifestyle habits such as smoking and alcohol abuse, are appropriate for all. Some individuals require calcium supplementation to their usual dietary intake and adequate vitamin D intake and/or supplementation are also needed. Appropriate risk assessment and evaluation is needed to determine appropriate treatment strategies in menopausal individuals. See Chapter 112, "Osteoporosis," for a full discussion of osteoporosis prevention and treatment.

Mood, Cognition, and Dementia

Menopausal hormone therapy improves depressive symptoms in symptomatic menopausal individuals, most likely by relieving hot flash and improving sleep. Those with vasomotor symptoms receiving MHT have improved mental health and fewer depressive symptoms compared with receiving placebo. However, MHT may worsen quality of life in individuals without flashes.[70]

More than 33% of females aged 65 years and older will develop dementia during their lifetime.[71] Several observational studies have suggested that estrogen therapy may be protective against Alzheimer's disease. The WHI Memory Study (WHIMS, an ancillary study of the WHI trial) evaluated the effect of MHT on dementia and cognition in 4,532 females participants aged 65 to 79 years.[72] The study found that postmenopausal individuals aged 65 years and older taking estrogen plus progestogen therapy had twice the rate of dementia, including Alzheimer disease, than those taking placebo (HR 2.05, 95% CI: 1.21-3.48).[72] In addition, estrogen plus progestogen therapy in these individuals did not prevent mild cognitive impairment, a cognitive and functional state between normal aging and dementia that frequently progresses to dementia.[72] The estrogen-alone arm of the WHI trial showed similar findings.[72,73]

In contrast, the Women's Health Initiative Memory Study of Younger Women (WHIMSY) found that neither estrogen plus progestogen or estrogen-alone therapy confers any risk or benefit to cognitive function when taken by postmenopausal individuals aged 50 to 55 years old.[74] In another study, the ancillary Cognitive and Affective Study (KEEPS-Cog) of the Kronos Early Estrogen Prevention Cognitive Study (KEEPS) evaluated the effects of up to four years of MHT on cognition and mood in recently menopausal participants (mean age 52.6 years and 1.4 years past FMP) with low cardiovascular risk.[75] Specifically, of the 693 participants, 220 were randomized to receive 0.45 mg/day oral CEE plus 200 mg/day micronized progesterone for the first 12 days of each month, 211 were randomized to receive 50 µg/day transdermal estradiol plus 200 mg/day micronized progesterone for the first 12 days of each month, and 262 were randomized to receive placebo pills and patches. After a mean length of follow-up of 2.85 years for cognition outcomes, no treatment-related benefits were observed. After a mean follow-up of 2.76 years regarding mood outcomes, model estimates indicated that those treated with oral CEE showed improvements in depression and anxiety symptoms over the 48 months of treatment, compared to those on placebo.[75]

Diabetes

In healthy postmenopausal females, hormone therapy has a beneficial effect on fasting glucose levels in individuals with elevated fasting insulin concentrations.[76] Also, in individuals with coronary artery disease, hormone therapy reduces the incidence of diabetes by 35%.[77] Participants who received estrogen plus progestogen in the WHI trial had a significant 21% reduction (HR, 0.79; 95% CI, 0.67-0.93) in the incidence of type 2 diabetes requiring treatment.[78] These findings provide important insights into the metabolic effects of hormone therapy but are insufficient to recommend the long-term use of hormone therapy in females with diabetes.

Body Weight

A meta-analysis of randomized controlled trials showed that unopposed estrogen or estrogen combined with a progestogen has no effect on body weight, suggesting that hormone therapy does not cause weight gain in excess of that normally observed at the time of menopause.[79]

Gallbladder Disease

Gallbladder disease is a commonly cited complication of oral estrogen use. The WHI studies reported an increased risk for cholecystitis, cholelithiasis, and cholecystectomy among participants taking oral estrogen or estrogen–progestogen therapy. Therefore, transdermal estrogen, which bypasses the liver's first-pass effect, is an alternative to oral therapy for individuals at high risk for cholelithiasis.[6]

Estrogens

Estrogens are naturally occurring hormones or synthetic steroidal or nonsteroidal compounds with estrogenic activity. The primary indication for systemic estrogen-based MHT is the relief of moderate and severe vasomotor and vulvovaginal symptoms. The initial dose should be the lowest effective dose for symptom control.

Adverse Effects

Common adverse effects of estrogen include nausea, headache, breast tenderness, and heavy bleeding. More serious adverse effects include increased risk for CHD, stroke, VTE, breast cancer, and gallbladder disease. Transdermal estradiol is associated with a lower incidence of breast tenderness and deep vein thrombosis than oral estrogen.[6,42]

Dosage and Administration

⑤ Use of MHT at doses lower than those prescribed historically (ie, prior to the WHI study) is effective in reducing bone loss and managing menopausal symptoms (see Table 102-1).[80–83] A dose of 0.625 mg/day in oral conjugated estrogen is equivalent to 1 mg/day of oral 17β-estradiol, which is equivalent to 0.05/day of transdermal estradiol.[84] Low-dose estrogen regimens include 0.3 mg conjugated estrogens, 0.5 mg micronized 17β-estradiol, and 0.014 to 0.0375 mg transdermal 17β-estradiol patch.[6] Topical gels, sprays, and creams are also available in low doses. Lower doses typically have fewer adverse effects and may have better overall benefit-risk profiles than standard doses. The lowest effective dose of estrogen, consistent with individualized patient treatment goals and assessment of safety and effectiveness, should be used.[48] With advancing age, dose of hormone therapy should be reduced or tapered.

Various systemically administered estrogens (typically oral and transdermal) are equally effective for replacement therapy (Table 102-4). Estrogens can be administered orally, percutaneously (transdermal patches and topical products), intravaginally (creams, tablets, rings, or inserts), intramuscularly, and even subcutaneously in the form of implanted pellets. The choice of estrogen delivery (product, route, and method) should be determined in consultation with the patient to ensure acceptability and enhance adherence. In general, the oral and transdermal routes are used most frequently.

TABLE 102-4

FDA-Approved Estrogen Products for Menopausal Hormone Therapy

Medication	Brand Name[a]	Initial Dose/Low Dose	Usual Dose Range	Comments

Systemic Estrogen Products (for the treatment of moderate and severe vasomotor symptoms ± urogenital symptoms)				
Oral estrogens[b]				
Conjugated equine estrogens	Premarin	0.3 or 0.45 mg once daily	0.3-1.25 mg once daily	Dosage form available as 0.3, 0.45, 0.625, 0.9, 1.25 mg
Esterified estrogens (75%-85% estrone + 6%-15% equilin)	Menest	0.3 mg once daily	0.3-1.25 mg once daily	Administer 3 weeks on and 1 week off
				Dosage form available as 0.3, 0.625, 1.25 mg
Micronized 17β-estradiol	Estrace generics	1 mg once daily	1 or 2 mg once daily	Administer 3 weeks on and 1 week off
				Dosage form available as 0.5, 1, 2 mg
Transdermal estrogens patches				
17β-Estradiol	Alora	0.025 mg/day (patch applied twice weekly)[c]	0.025-0.1 mg/day (patch applied twice weekly)[c]	Dosage form available as 0.025, 0.05, 0.075, 0.1 mg/day
	Climara	0.025 mg/day (patch applied once weekly)[c]	0.025-0.1 mg/day (patch applied once weekly)[c]	Dosage form available as 0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg/day
	Menostar	0.014 mg/day (patch applied once weekly)[c,d]	0.014 mg/day (patch applied once weekly)[c,d]	Dosage form available as 0.014 mg/day
	Minivelle, Vivelle, Vivelle Dot	0.025 mg/day (patch applied twice weekly)[c]	0.025-0.1 mg/day, 0.05 is standard dose (patch applied twice weekly)[c]	Dosage form available as 0.025, 0.0375, 0.05 (standard dose), 0.075, 0.1 mg/day
Other topical forms of estrogen				
17β-Estradiol topical gel	EstroGel 0.06% metered-dose pump	–	1.25 g/day once daily (contains 0.75 mg estradiol)	Apply from wrist to shoulder
	Elestrin 0.06% metered-dose pump	–	1-2 unit doses once daily (1 unit dose: 0.87 g, which contains 0.52-mg estradiol)	Apply to upper arm

	Divigel 0.1% (topical once daily)	0.25 g once daily	0.25-1 g (provides 0.25-1 mg of estradiol)	Apply to upper thigh. Dosage form available as 0.25, 0.5, 0.75, 1 mg
17β-Estradiol transdermal spray	Evamist	1 spray once daily	1-3 sprays once daily (1.53 mg of estradiol per spray)	Apply to inner surface of forearm
Vaginal estrogens				
Estradiol acetate vaginal ring	Femring	12.4 mg every 3 months	12.4-, 24.8-mg ring (delivers 0.05- or 0.1-mg estradiol/day)	
Intravaginal Estrogen Products (for the treatment of urogenital symptoms only/low systemic exposure)				
Conjugated equine estrogens (CEE) vaginal cream	Premarin		0.5-2 g/day (contains 0.625 mg CEE per g)	Administer 21 days on and 7 days off
17β-Estradiol vaginal cream	Estrace	500 mg to 1 g daily for 2 weeks, then 500 mg to 1 g one to three times weekly; or 2-4 g daily for 1 or 2 weeks then gradually reduced to ½ initial dosage for similar period	Maintenance dose of 0.5-1 g, one to three times weekly	Dosage form available as tube containing 1½ oz (45 mL) with calibrated applicator for delivery of 1, 2, 3, or 4 g
17β-Estradiol vaginal ring	Estring	2 mg ring replaced every 90 days	2 mg ring (delivers 0.0075 mg/day) replaced every 90 days	
17β-Estradiol vaginal insert	Imvexxy	1 vaginal insert (4µg) daily for 2 weeks, then reduce to 1 insert twice weekly	4 or 10 µg twice weekly, every 3-4 days	
Estradiol hemihydrate vaginal tablet	Vagifem	10 µg once weekly for 2 weeks, then twice weekly	10 µg twice weekly	
	Yuvafem			
	Generics			

[a] US brand names.

[b] Orally administered estrogens stimulate synthesis of hepatic proteins and increase circulating concentrations of sex hormone-binding globulin, which in turn may compromise the bioavailability of androgens and estrogens. Individuals with elevated triglyceride concentrations or significant liver function abnormalities are candidates for nonoral estrogen therapy.

[c] Do not apply estrogen patches on or near breasts. Avoid waistline as patch may rub off with tight-fitting clothing.

[d] FDA-approved for prevention of postmenopausal osteoporosis only.

[e]Not available in the United States.

Oral Estrogen

Oral conjugated equine estrogen has been available for more than 70 years. Oral CEE is prepared from the urine of pregnant mares and is composed of estrone sulfate (50%-60%) and multiple other equine estrogens such as equilin and 17α-dihydroequilin.

Estradiol is the predominant and most active form of endogenous estrogens. A micronized form of estradiol (produced by a technique that yields extremely small particles of the pure hormone) is readily absorbed from the small intestines. When given orally, estradiol is metabolized by the intestinal mucosa and the liver during the first hepatic passage, and only 10% reaches circulation as free estradiol. Metabolism of estrogen is partly mediated by the cytochrome P450 3A4 isoenzyme. Gut and liver metabolism converts a large proportion of estradiol to the less-potent estrone. Thus, measurement of serum estradiol is not useful for monitoring oral estrogen replacement. The principal metabolites of micronized estradiol are estrone and estrone sulfate. Administration of estradiol via the oral route results in estrone concentrations that are five to seven times those of estradiol. Ethinyl estradiol is a highly potent semisynthetic estrogen that has similar activity following administration by the oral or nonoral route.

Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens.

Other Routes of Estrogen Administration

Nonoral routes of estrogen administration may offer both advantages and disadvantages compared with the oral route, but long-term data are not available. As the nonoral forms of estrogens bypass the GI tract, they thereby avoid first-pass liver metabolism. These routes of estradiol delivery result in a more physiologic estradiol-to-estrone ratio (estradiol concentrations greater than estrone concentrations), as seen in the normal premenopausal state.

⑥ When compared with standard oral estrogen doses, transdermal therapy offers no significant increase in triglycerides, C-reactive protein, sex hormone binding globulin, and blood pressure.[6] Use of transdermal estrogen has also been associated with a lower risk of deep vein thrombosis and possibly stroke and coronary artery disease.[6,21,25] Transdermal estrogen patches share the advantages of other nonoral estrogen routes and have the added advantage of delivering estradiol to the general venous circulation at a continuous rate. The matrix transdermal systems (estrogen in adhesive) generally are well tolerated, and fewer than 5% of individuals experience skin reactions. The incidence of skin irritation diminishes when the application site is rotated. Topical anti-inflammatory products (eg, hydrocortisone cream) can be applied for managing the rashes, and switching to another transdermal patch is often a viable option.

Topical gels, sprays, and emulsions are convenient forms of systemic estrogen therapy, but variability in drug absorption has been noted with some formulations. Intravaginal creams, tablets, inserts, and rings are used for treatment of urogenital (vulvar and vaginal) atrophy. Pharmacologically they are sustained-release delivery systems that can maintain adequate estradiol concentrations. While most products provide local estrogen, one intravaginal-ring product (Femring®) is designed to achieve systemic concentrations of estrogen and is also indicated for treatment of moderate-to-severe vasomotor symptoms. Estradiol pellets (for subcutaneous implantation), containing pure crystalline 17β-estradiol, have been available for more than 60 years. They are inserted subcutaneously into the anterior abdominal wall or buttock. Pellets are difficult to remove and may continue to release estradiol for a long time after insertion. Implantation should not be repeated until serum estradiol concentrations have fallen to values similar to those at the midfollicular phase of the menstrual cycle. Although FDA-approved estradiol pellets are not available in the United States, some healthcare providers prescribe and implant compounded bioidentical hormone pellet therapy.[84]

Progestogens

Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (ie, unopposed estrogen), use of systemic estrogen in individuals with an intact uterus must always be accompanied by a progestogen or tissue-selective estrogen complex (estrogen/bazedoxifene) for endometrial protection.[85] Some data suggest that progestins may also improve vasomotor symptoms,[86,87] but their use for this purpose is not considered first-line or standard therapy.

Progestogens reduce nuclear estradiol receptor concentrations, suppress DNA synthesis, and decrease estrogen bioavailability by increasing the activity of endometrial 17-hydroxysteroid dehydrogenase, an enzyme responsible for converting estradiol to estrone.[88]

The term progestogen is a catch-all term that includes both progesterone products that are structurally identical to the hormone produced by the body and synthetic progestins that have progestogenic effects but are structurally different than the natural hormone.[89] The first generation of progestins included the C-19 androgenic progestin norethindrone (also known as norethisterone), norgestrel, and levonorgestrel. More recent preparations have included the C-21 progestins dydrogesterone (not currently available in the United States) and medroxyprogesterone acetate (MPA), which are less androgenic. Drospirenone, a synthetic progestin analog of the potassium-sparing diuretic spironolactone, has both antiandrogenic and antialdosterone properties. Micronized progesterone is also available and is structurally identical to the natural hormone. The most commonly used oral progestogens are MPA, micronized progesterone, and norethindrone acetate.[90] The latter can also be administered transdermally in the form of a combined estrogen–progestogen patch. Preparations contain MPA have shown to have higher thrombotic risks.[48]

Although data are limited, oral micronized progesterone and dydrogesterone (not currently available in the United States) are considered as the first-line progestogens (safe alternative) because it is effective for endometrial hyperplasia, is metabolically neutral, and does not increase the risk of either breast cancer or CHD in studies to date.[91]

Adverse Effects

Common adverse effects of progestogens include irritability, weight gain, bloating, and headache. Changing from a cyclic to a continuous-combined regimen or changing from one progestogen to another may decrease the incidence or severity of untoward effects. Adverse effects of progestogens are difficult to evaluate and can vary with the agent administered. Some individuals experience “premenstrual-like” symptoms, such as mood swings, bloating, fluid retention, and sleep disturbance. Newer methods and routes of progestogen delivery (eg, locally by an intrauterine device that releases levonorgestrel or a progesterone-containing bioadhesive vaginal gel) may be associated with fewer adverse effects.

Dosage and Administration

Several progestogen regimens designed to prevent endometrial hyperplasia are available for use in individuals with an intact uterus (Table 102-5). Progestogens can be used continuously (resulting in endometrial atrophy) or cyclically (resulting in monthly withdrawal bleeding). For cyclic use, the progestogen must be taken for a sufficient period of time during each cycle. In general, a minimum of 12 to 14 days of progestogen therapy per month is required for complete protection against estrogen-induced endometrial hyperplasia. For individuals with a history of hysterectomy, use of progestogens is not needed. However, in individuals with endometriosis who have had a hysterectomy, the use of a progestogen along with estrogen may minimize endometriosis exacerbations.

TABLE 102-5

Progestogen Dosing for Endometrial Protection (Cyclic Administration)

Progestogen	Dosage
Medroxyprogesterone acetate	5-10 mg/day for 12-14 days per calendar month (oral dosage form available as 2.5-, 5-, 10-mg tablets)
Micronized progesterone	200 mg/day for 12-14 days per calendar month (oral dosage form available as 100- and 200-mg tablets)
Norethindrone acetate	5 mg/day for 12-14 days per calendar month (oral dosage form available as 2.5-, 5-mg tablets)

Menopausal Hormone Therapy Regimens

Many products have been used for MHT, and most include an estrogen and a progestogen in various regimens, routes, and administration schedules. Continuous combined hormone regimen with synthetic progestin reduce the risk of endometrial cancer whereas sequential combined hormone regimen with synthetic progestin and continuous combined and sequential combined with natural progestins increase the risk of endometrial cancer depending on the dose and duration of use.[64] Additionally, tissue-selective estrogen complex product (estrogen/bazedoxifene) is available for once-daily dosing. Common combination MHT regimens are described in Table 102-6.

TABLE 102-6

Common Combination Menopausal Hormone Therapy Regimens

Regimen	Brand name	Dosage
Oral Regimens		
Conjugated equine estrogen (CEE) + medroxyprogesterone acetate (MPA)	Prempro (continuous)	0.625 mg CEE/2.5 mg MPA, 0.625 mg CEE/5 mg MPA daily Low-dose: 0.3 mg CEE/1.5 mg MPA, 0.45 mg CEE/1.5 mg MPA daily
	Premphase (continuous cyclic)	0.625 mg CEE daily only in the first 2 weeks of a 4-week cycle then 0.625 mg daily CEE + 5 mg MPA daily in the last 2 weeks of a 4-week cycle
Conjugated equine estrogen (CEE) + bazedoxifene	Duavee (continuous)	0.45/20 mg daily
Ethinyl estradiol (EE) + norethindrone acetate (NETA)	Generic, Femhrt (continuous) Fayvolv (continuous)	Femhrt: 2.5 µg EE/0.5 mg NETA daily Fyavolv: 2.5 µg EE/0.5 mg NETA daily, 5 µg EE/1 mg NETA daily
Estradiol (E) + drospirenone (DRSP)	Angeliq (continuous)	1 mg E/0.5 mg DRSP daily Low dose: 0.5 mg E/0.25 mg DRSP daily
Estradiol (E) + norgestimate	Prefest (estrogen/intermittent progestogen)	1 mg E daily for first 3 days then 1 mg E/0.09 mg norgestimate daily for next 3 days; this pattern is repeated continuously
Estradiol (E) + norethindrone acetate (NETA)	Activella (continuous) Mimvey (continuous) Amabelz (continuous)	1 mg E/0.5 mg NETA daily Low-dose: 0.5 mg E/0.1 mg NETA daily
Estradiol (E) + progesterone	Bijuva (continuous)	1 mg E/100 mg progesterone daily
Transdermal Regimens		
Estradiol + norethindrone acetate patch	CombiPatch (continuous) CombiPatch (continuous cyclic)	Continuous: 0.05/0.14 mg, 0.05/0.25 mg (apply 1 patch twice weekly) Continuous cyclic: 0.05 mg of an estradiol only patch (apply 1 patch twice weekly) in the first 2 weeks of a 4-week cycle then either dose of the CombiPatch (apply 1 patch twice weekly) in the last 2 weeks of a 4-week cycle
Estradiol (E) + levonorgestrel patch	Climara Pro (continuous)	0.045 mg E/0.015 mg/day (apply 1 patch once weekly)

CEE, conjugated equine estrogen; DRSP, drospirenone; E, estradiol; EE, ethinyl estradiol; NETA, norethindrone acetate; MPA, medroxyprogesterone acetate.

Cyclic (Sequential) Estrogen–Progestogen Treatment

Estrogen typically is administered continuously (daily). A progestogen is coadministered with the estrogen for 12 to 14 days of a 28-day cycle.[90] The progestogen causes scheduled withdrawal bleeding in approximately 80% to 90% of users. With this regimen, bleeding usually begins 1 to 2 days after the last progestogen dose. Occasionally, bleeding begins during the latter phase of progestogen administration.

Continuous Combined Estrogen–Progestogen Treatment

Continuous combined estrogen–progestogen administration (both estrogen and progestogen are administered daily) results in endometrial atrophy and the absence of vaginal bleeding. Continuous combined MHT is more acceptable than traditional cyclic therapy if individuals prefer to avoid the monthly withdrawal bleeding. However, unpredictable spotting or bleeding may occur initially, which usually resolves within 6 to 12 months. Individuals who recently have undergone menopause have a higher risk for excessive, unpredictable bleeding while receiving continuous therapy; thus, this regimen is best reserved for those who are at least 2 years postmenopausal. This method of treatment can be achieved by using either commercially available oral and transdermal preparations or by administering systemic estrogen along with the use of the levonorgestrel-releasing intrauterine system. This combination offers the best protection against endometrial hyperplasia and cancer.[21] The continuous combined estrogen–progestogen regimen (using conjugated equine estrogens 0.625 mg/day plus medroxyprogesterone acetate 2.5 mg/day) led to a decreased risk of endometrial cancer in the WHI study.[16]

Intermittent Combined Estrogen–Progestogen Treatment

The intermittent combined estrogen–progestogen regimen, also called *continuous-pulsed estrogen–progestogen* or *pulsed-progestogen*, consists of 3 days of estrogen therapy alone, followed by 3 days of combined estrogen and progestogen, which is then repeated without interruption. This regimen is designed to lower the incidence of uterine bleeding. It is based on the assumption that pulsed-progestogen administration will prevent downregulation of progesterone receptors that can be produced by continuous combined regimens. The lower progestogen dose induces fewer adverse effects and can be better tolerated. The long-term effect of intermittent combined regimens in endometrial protection is undetermined.

Compounded Bioidentical Hormone Therapy

Bioidentical hormone products are those that contain hormones that are chemically identical molecules to those produced by the body. There are FDA-approved products containing bioidentical hormones (eg, 17β-estradiol, progesterone). Compounded bioidentical hormone therapy (CBHT) is terminology used to describe hormone therapy formulations that are custom-prepared (ie, compounded) for individual patients, often involving the use of measuring and monitoring hormone levels in blood and/or other body fluids such as saliva.[25] Hormones that are commonly used in CBHT include estrone, estradiol, estriol, progesterone, testosterone, DHEA, and thyroid hormone. Although claims have been made to suggest that compounded bioidentical hormones are safer and more “natural” alternatives to commercially available preparations, there is a paucity of evidence regarding the efficacy, safety, and pharmaceutical quality of these products. Furthermore, saliva testing is often used to adjust hormone levels, and there is no scientific evidence to support this practice. Bioidentical hormones carry the same risks as traditional hormone therapy products. Several major medical organizations have released statements to dissuade patients and clinicians from CBHT and its use is only recommended only when there is a medical need for an unusual dosing regimen or ingredients or when patients have allergies to FDA-approved therapies.[6,25,92,93]

Other Treatments for Menopause-Related Symptoms

In individuals who have contraindications to MHT use, prefer not to take estrogen and/or progestogen, or cannot tolerate estrogen and/or progestogen administration, a number of other medications may be considered, depending on the goals of therapy.[6,17,19] These include the prescription medications testosterone, SERMs, and tibolone as well as nonhormonal prescription medications (eg, selective serotonin reuptake inhibitors). Tibolone is a gonadomimetic synthetic steroid in the norpregnane family with combined estrogenic, progestogenic, and androgenic activity. It has been in use for several decades in Europe for the treatment of menopausal symptoms and prevention of osteoporosis but is currently not approved in the United States.

Alternatives to estrogen for treatment of hot flashes include selective serotonin reuptake inhibitors (eg, paroxetine, fluoxetine, citalopram, escitalopram), dual serotonin and norepinephrine reuptake inhibitors (eg, venlafaxine, desvenlafaxine), clonidine, gabapentin, and pregabalin (Table 102-7). Progestogens (eg, MPA, megesterol acetate) alone may be an option for some individuals (eg, those with a history of VTE), but weight gain, vaginal bleeding, and other adverse effects often limit their use. Progestogens cannot be considered nonhormonal agents for the treatment of hot flashes for individuals in whom MHT is contraindicated. For this group of patients, selective serotonin reuptake inhibitors such as paroxetine mesylate and serotonin-norepinephrine reuptake inhibitors such as venlafaxine are considered by some to be a first-line therapy.[17] However, in breast cancer patients, certain selective serotonin reuptake inhibitors (paroxetine and fluoxetine) could interfere with metabolism of endocrine therapies, such as tamoxifen via cytochrome P450 2D6 inhibition (tamoxifen requires activation to its active metabolites by cytochrome P450 2D6).[17,21] Gabapentin has demonstrated beneficial effect for reducing the frequency and severity of vasomotor symptoms. Higher effective doses may limit its use due to adverse events at such doses; including drowsiness, dizziness, and loss of coordination. However, it may be a reasonable option for individuals with disrupted sleep and hot flashes when administered in the evening. Pregabalin has demonstrated benefit at alleviating vasomotor symptoms, but is less well studied.[21] Clonidine has also been shown to be more effective for hot flashes compared to placebo but its adverse effects (eg, sedation, dry mouth, and hypotension) are not always well tolerated. It is also less effective than the previously described nonhormonal treatment options.[21]

TABLE 102-7

Alternatives to Estrogen for Treatment of Hot Flashes[a]

Medication	Brand Name[b]	Initial Dose	Usual Dose Range	Comments
Venlafaxine	Effexor, Effexor XR	37.5 mg	37.5-75 mg/day	Adverse effects include nausea, headache, somnolence, dizziness, insomnia, nervousness, xerostomia, anorexia, constipation, diaphoresis, weakness, and hypertension
Desvenlafaxine	Pristiq	50 mg	50-100 mg/day	Adverse effects include nausea, headache, somnolence, dizziness, insomnia, xerostomia, anorexia, constipation, diaphoresis, and weakness
Paroxetine, paroxetine CR[c]	Brisdelle,[d] Paxil, Paxil CR, Pexeva	7.5 mg/day (Brisdell formulation),[d] 10 mg/day (paroxetine), or 12.5 mg/day (paroxetine CR)	7.5 mg/day,[d] 10-20 mg/day or 12.5–25 mg/day	Adverse effects include nausea, somnolence, insomnia, headache, dizziness, xerostomia, constipation, diarrhea, weakness, and diaphoresis
Citalopram		10 mg/day	10-20 mg/day	Adverse effects include drowsiness, insomnia, diaphoresis, nausea, xerostomia, dose-dependent QTc prolongation
Escitalopram		10 mg/day, start with 5 mg/day in sensitive or older individuals and titrate up	10-20 mg/day	Adverse effects include headache, insomnia, nausea, increased sweating, fatigue, and somnolence. Decreased libido and anorgasmia
Clonidine patch	Catapres-TTS (transdermal)	0.1 mg/day (0.1 mg/24 hour patch)	0.1 - 0.3 mg/day (available as 0.1, 0.2, or 0.3 mg/24 hour patch)	Adverse effects include drowsiness, dizziness, hypotension, and dry mouth, especially with higher doses
Pregabalin	Lyrica	50 mg/day	75-150 mg twice/day	Adverse effects include drowsiness, dizziness, dry mouth, edema, blurred vision, weight gain, impaired concentration
Gabapentin	Gralise, Neurontin, generics	300 mg at bedtime	900 mg/day (divided in three daily doses), doses up to 2,400 mg/day (divided in three daily doses) have been studied	Adverse effects include somnolence and dizziness; these symptoms often can be obviated with a gradual increase in dosing

CR, controlled release; XR, extended release.

[a] Treatment of postmenopausal hot flashes is an off-label indication in the United States for all medications listed except for one formulation of paroxetine (paroxetine mesylate).

[b] US brand names.

Other selective serotonin reuptake inhibitors (eg, citalopram, escitalopram, fluoxetine, and sertraline) have also been studied and may be used for the treatment of hot flashes.

The brand Brisdelle contains 7.5 mg of paroxetine and is FDA-approved to treat moderate-to-severe vasomotor symptoms of menopause. This specific product is not FDA-approved for treating psychiatric conditions.

Androgens

The therapeutic use of testosterone in females is controversial. In the United States, there are currently no testosterone products FDA-approved for use in females. Androgens have important biologic effects in females, acting both directly via androgen receptors in tissues, such as bone, skin fibroblasts, hair follicles, and sebaceous glands, and indirectly via the aromatization of testosterone to estrogen in the ovaries, bone, brain, adipose tissue, and other tissues. There is a natural decline in androgen production with aging, and pathophysiologic states affecting ovarian and adrenal function, such as adrenal insufficiency and hypopituitarism, as well as bilateral oophorectomy, are associated with androgen deficiency in females. Androgens are produced by both the adrenal glands and the ovaries in females and include 5α-dihydrotestosterone, androstenedione, dehydropepiandrosterone (DHEA), dehydropepiandrosterone-sulfate (DHEA-S), and testosterone. A cluster of symptoms that characterizes androgen insufficiency in females, manifested as diminished sense of well-being, persistent or unexplained fatigue, and sexual function changes such as decreased libido, decreased sexual receptivity, and decreased pleasure has been reported.[12] A recent meta-analysis of 36 randomized, controlled trials involving 8,480 postmenopausal females concluded that testosterone therapy significantly improved sexual function in those with low sexual desire causing distress, when compared to placebo or estrogen/estrogen-progestogen therapy.[10] In 2019 the Global Consensus Position Statement on the Use of Testosterone Therapy for Females was published and endorsed by 11 professional societies across the world, including the North American Menopause Society, and in 2021, a clinical practice guideline was published.[39,94] The guideline recommends that testosterone therapy can be considered in postmenopausal females with hypoactive sexual desire disorder causing significant distress, after thoroughly discussing the risks and benefits and obtaining informed consent. If an approved female formulation is not available, the guideline recommends using one-tenth of a standard male dose of 1% transdermal testosterone or about 300 µg/day to achieve the normal premenopausal physiological range. However, compounded products are not recommended. Transdermal (patch, gel, cream, or spray) formulations are preferred and oral and intramuscular formulations are not recommended due to the possibility of supraphysiologic testosterone levels and adverse effects. Patients on testosterone therapy should be closely monitored for both efficacy and safety.[39] Effects from excessive testosterone dosage include virilization, acne, hair growth, fluid retention, weight gain, and lipid effects (increase in LDL-cholesterol and decrease in total cholesterol, triglyceride, and HDL-cholesterol). The lipid effects have been reported with oral but not with transdermal testosterone products.[95] Androgenic effects of testosterone therapy are rare when the testosterone level does not exceed the premenopausal range.[39] Further studies are required to determine the long-term (>24 months) safety of testosterone in females including effects on breast cancer and cardiovascular risks.[39] Androgens should not be used during pregnancy or lactation or in individuals with suspected androgen-dependent neoplasia.

Dehydroepiandrosterone (DHEA)

DHEA is a precursor hormone in the synthesis of estrone, estradiol, and testosterone and is classified as a dietary supplement in the United States. It has been used off-label for a number of conditions, including fertility and treatment of menopausal symptoms. Intravaginal DHEA (cream, gel, suppositories) was previously only available as compounded formulations but a prescription version (in the form of an insert) has been approved by the FDA for treatment of moderate-to-severe dyspareunia at a dose of 6.5 mg once daily at bedtime. Premarketing clinical trials reported a significant improvement in moderate-to-severe dyspareunia symptoms and decrease in vaginal dryness compared to placebo.[96] Intravaginal administration of prasterone conveys only a local effect on the vaginal tissue; the serum concentrations of estradiol, testosterone, and DHEA were within the normal range for postmenopausal participants after 12 weeks of treatment in one clinical trial.[97] Prasterone's FDA labeling does not carry the same boxed warnings for VTE, endometrial hyperplasia, or other risks that are present in estrogen-containing products. However, the product labeling does warn against the use of prasterone in individuals with a history of, or suspected, breast cancer, given that prasterone is a precursor to estrogen. Prasterone is also contraindicated in individuals with undiagnosed AUB. The most common adverse effects of intravaginal prasterone are vaginal discharge and abnormal Pap smear.[98]

Selective Estrogen Receptor Modulators (SERMs)

Selective estrogen receptor modulators are a group of nonsteroidal compounds that are chemically distinct from estradiol. They act as estrogen agonists in some tissues, such as bone, and as estrogen antagonists in other tissues, such as breast and endometrial tissue, through specific, high-affinity binding to the estrogen receptor. Individual SERMs differ in their activity and tissue specificity resulting in varying patterns of estrogen-receptor agonism in some tissues and estrogen-receptor antagonism in others.[99]

The ideal SERM would protect against osteoporosis and decrease the incidence of breast, endometrial, and colorectal cancer and CHD without exacerbating menopausal symptoms or increasing the risk of VTE or gallbladder disease. To date, no SERM meets these ideals. Tamoxifen, the first-generation SERM (a nonsteroidal triphenylethylene derivative), has estrogen antagonist activity on the breast and estrogen-like agonist activity on bone and endometrium. The second-generation SERM raloxifene, a nonsteroidal benzothiophene derivative, is used to reduce the risk of postmenopausal osteoporosis and invasive breast cancer, and also for treatment of postmenopausal osteoporosis. Raloxifene is antiestrogenic at the endometrium and has an increased incidence of hot flashes compared to placebo.[100]

The third-generation SERM, bazedoxifene, in conjunction with conjugated estrogens forms a tissue-selective estrogen complex (TSEC) and is FDA-approved for use in moderate-to-severe vasomotor symptoms and prevention of osteoporosis.[99,101] This agent has a favorable breast, endometrial, and ovarian safety profile, even after prolonged use.[11] While this TSEC has demonstrated high effectiveness for vasomotor symptoms (approximately 75% reduction),[11,102] SERMs alone do not alleviate, and may even exacerbate vasomotor symptoms, and also increase the risk for VTE.

Ospemifene is an orally administered third-generation SERM approved by the FDA for the treatment of moderate-to-severe dyspareunia and moderate-to-severe vaginal dryness from menopausal vulvar and vaginal atrophy due to menopause. Ospemifene's labeling carries a boxed warning about its estrogenic effect on the endometrium as there is an increased risk of endometrial hyperplasia and endometrial cancer in a individuals with a uterus who takes unopposed estrogen therapy. Ospemifene labeling also includes a boxed warning about the possible risk of stroke and VTE.[103]

Adverse Effects

Depending on the tissue selectivity, several SERMs are associated with hot flashes and less often with leg cramps. The SERMs can increase the risk of VTE and fatal stroke to a degree similar to that of oral estrogen, but the degree of risk is product specific.[6] Common adverse effects (greater than or equal to 5%) of bazedoxifene include muscle spasms, nausea, diarrhea, dyspepsia, upper abdominal pain, oropharyngeal pain, dizziness, and neck pain.[104] Common adverse effects of ospemifene include hot flashes, vaginal discharge, muscle spasm, headache, vaginal hemorrhage, and hyperhidrosis.[103]

Dose and Administration

Conjugated estrogens/bazedoxifene is supplied as 0.45/20-mg tablets and is taken once daily. Ospemifene is a 60-mg tablet taken once daily with food. Other available SERMs are also dosed orally once daily.

Complementary and Alternative Medicine

Some patients prefer to use natural remedies due to a belief that they are safer. However, randomized, placebo-controlled trials of complementary and alternative therapies have been equivocal and have not established the safety and efficacy of herbal remedies, homeopathic treatments, or acupuncture for the prevention or treatment of hot flashes.

Phytoestrogens

Phytoestrogens are plant compounds with estrogen-like biologic activity and relatively weak estrogen receptor-binding properties, resulting in physiologic effects in humans. Epidemiologic studies suggest that consumption of a phytoestrogen-rich diet, which is common in traditional Asian societies, may be associated with a lower risk of endometrial and ovarian cancer.[105]

The biologic potencies of phytoestrogens vary as most of these compounds are nonsteroidal and are less potent than synthetic estrogens. The main classes of phytoestrogens are isoflavones, lignans, coumestans, and prenylflavonoids.[105] The most commonly studied phytoestrogen is the isoflavone class, with genistein and daidzein being the most abundant active components of isoflavones. The concentration of isoflavones per gram of soy protein varies considerably among preparations. Also, a single plant often contains more than one class of phytoestrogen. Common food sources of phytoestrogens include soybeans (isoflavones), oilseeds such as flaxseed (lignans), alfalfa sprouts and pinto beans (coumestans), and hops and beer (prenylflavonoids).[105]

Mild estrogenic effects have been seen in postmenopausal individuals with phytoestrogen consumption. A systematic review indicated that high levels of genistein extracts reduce the number of daily hot flashes compared with placebo without harmful endometrial effects when used for up to 2 years.[106] A limitation of this review is that many of the studies included were of poor quality and short duration. A more recent meta-analysis of randomized, controlled trials concluded that compared to placebo, phytoestrogens reduce the frequency of hot flashes and vaginal dryness but not in night sweats.[107]

Phytoestrogens decrease low-density lipoprotein (LDL) cholesterol and triglyceride concentrations with no significant change in HDL cholesterol concentrations.[108] Furthermore, phytoestrogens have the ability to inhibit LDL oxidation and normalize vascular reactivity in estrogen-deprived primates.108 Common adverse effects include constipation, bloating, and nausea.[109]

A meta-analysis reported that phytoestrogen use is not associated with increased rates of endometrial cancer, vaginal bleeding, and breast cancer.[109] Large, long-term studies are needed to further document the effects of phytoestrogens on the breast, bone, and endometrium. Furthermore, before phytoestrogens can be considered an alternative to conventional MHT in postmenopausal individuals, additional data are needed to clarify differences among classes of phytoestrogens, including dosing, biologic activity, safety, and efficacy.

Other Complementary and Alternative Options

Black cohosh (*Cimicifuga racemosa* or *Actaea racemosa*), a widely used herbal supplement, may not offer substantial benefits for relief of vasomotor symptoms. A systematic review and meta-analysis concluded that black cohosh was not associated with a reduction in hot flashes.[107] This substance does not have strong intrinsic estrogenic properties but may act through the serotonergic system. Although it is generally well tolerated, hepatotoxicity has been reported and it is unclear if this is due to the herb itself or is a result of adulteration of the commercially available products.[110] The long-term effects of black cohosh are unknown. Other herbals and alternative treatments that may be used include dong quai, red clover leaf (contains phytoestrogens), and ginseng. These have not been shown to be effective in the treatment of menopausal symptoms and may carry the risk of adverse events.[6,107,111] Complementary and alternative therapies should not be recommended to treat menopausal symptoms.

Personalized Pharmacotherapy

⑧ The severity of menopausal symptoms varies widely between individuals. The decision to use MHT must be personalized and based on several parameters, including vasomotor and vulvovaginal symptoms, age, fracture risk, cardiovascular disease risk, breast cancer risk, and thromboembolism risk. MHT is not indicated for prevention of chronic diseases of aging and it's initiation should be considered for healthy symptomatic individuals who are within 10 years of the onset of menopause or younger than 60 years and who do not have contraindications to therapy.[6,23] The treatment regimen (estrogen only or combined estrogen–progestogen, dose, route of administration) and duration should be based on the individualized risk versus benefit analysis for each patient.[16]

Long-term use of MHT or initiation in older individuals is associated with greater risks. Once advised of increased risks associated with continuing MHT beyond age 60 years, extending therapy may be acceptable under close medical supervision. For example, in those with severe and persistent menopausal symptoms, use should not be discontinued based solely on age but rather individualized based on assessment of potential risks and benefits.[6]

Estrogen therapy is the most effective treatment for moderate and severe vasomotor symptoms, impaired sleep quality, and vulvovaginal symptoms of menopause (Fig. 102-1). A thorough discussion of the risks and benefits of MHT should be completed with the patient so that they can weigh the risks and benefits versus alternatives and make a rational decision about MHT use. For a healthy recently menopausal individuals with vasomotor symptoms, the benefits of hormonal therapy generally outweigh the risks, including control of vasomotor symptoms, treatment of urogenital atrophy, and prevention of postmenopausal bone loss. Nonetheless, VTE and stroke are concerning short-term risks.

Menopausal hormone therapy should be tailored for optimal formulation, dose, route of delivery, and counseling should be based on age, years since menopause, and hysterectomy status. All types and routes of administration of estrogen are equally effective in relieving vasomotor symptoms and vulvovaginal atrophy.[6] A dose-dependent relationship between estrogen administration and suppression of hot flashes is well established. Some females, especially younger individuals, may require a higher than average dose of estrogen to suppress symptoms, while those with hot flashes at the time of menopause require lower estrogen doses.[112] Initiation of therapy with low doses of estrogen often will minimize adverse effects, such as breast tenderness and unscheduled bleeding. Transdermal estradiol is less likely than oral estrogen to cause nausea and headache. In many cases changing from one estrogen regimen to another can alleviate certain adverse effects.

If MHT is to be initiated, the selection of the drug should also take into account the potential for medication interactions, including those involving the cytochrome P450 (CYP450) microsomal enzyme system. For example, the CYP450 isoenzyme 3A4, metabolizes estrogen, the SERM ospemifene, and the progestin medroxyprogesterone. Inducers or inhibitors of these enzymes may either decrease or increase, respectively, therapeutic effects or result in adverse effects. Similarly, selection of nonhormonal drug therapy options should take into account the potential for interactions with other prescription and nonprescription medications the patient may be taking. Selective serotonin reuptake inhibitors and serotonin norepinephrine reuptake inhibitors can have major interactions with other drugs also affecting CYP450 2D6 and 3A4 (see Chapter 88, "Depressive Disorders"). Patients using vaginal estrogen creams or nonestrogen vaginal moisturizers should be warned that products with oil-based lubricants or vehicles can weaken latex condoms, which can decrease protection against sexually transmitted infections. Pharmacodynamic drug interactions (eg, additive adverse effects) should also be considered.

EVALUATION OF THERAPEUTIC OUTCOMES

The relief of moderate and severe hot flashes is the primary goal of MHT. In order to adequately assess treatment effect, individuals should be encouraged to continue their MHT regimen for at least 1 month. The main reasons for discontinuing MHT are adverse effects such as bleeding, breast tenderness, bloating, and "premenstrual-like symptoms." Reducing the dose or changing the regimen or the route of administration can minimize these effects. Alternatively, if vasomotor symptoms are not controlled adequately with a lower-dose regimen, increasing the estrogen dose may be a reasonable option. Therefore, after the menopausal individual begins MHT, a brief follow-up visit 6 weeks later may be useful to discuss patient concerns about MHT and to evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding. Individuals receiving MHT should be seen by the clinician for annual monitoring (Table 102-8).

TABLE 102-8

Management of Patients Taking Hormone Therapy Regimens

Initiation of Hormone Therapy			
Hormone therapy should be used only as long as vasomotor symptom control is necessary			
Six-Week Follow-up Visit			
• To discuss patient concerns about hormone therapy • To evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding (if continuous sequential hormone therapy is given)			
Drug	**Common Adverse Reactions**	**Monitoring Parameter**	**Suggested Change**
Estrogen		Persistence of hot flashes	Increase estrogen dose
Estrogen	Breast tenderness		Reduce estrogen dose; switch to a transdermal regimen
Progestogen	Bloating		Switch to another progestogen or bazedoxifene
	Premenstrual-like symptoms		
Annual Follow-up Visit			
Annual monitoring: medical history, physical examination (including pelvic examination), blood pressure measurement, and routine endometrial cancer surveillance (as indicated). Additional follow-up is determined based on the patient's initial response to therapy and the need for any modification of the regimen			
Breast examinations: annual mammograms (scheduled based on patient's age and risk factors)			
Osteoporosis prevention: BMD should be measured in individuals 65 years and older and in those younger than 65 years with risk factors for osteoporosis. Repeat testing should be performed as clinically indicated.			
In individuals taking sequential hormone therapy	Transvaginal ultrasound, and where indicated an endometrial biopsy should be performed if vaginal bleeding occurs at any time other than the expected time of withdrawal bleeding or when heavier or more prolonged withdrawal bleeding occurs (if endometrial pathology cannot be excluded by endovaginal ultrasonography, further evaluation may be required, such as hysteroscopy)		
In individuals taking continuous combined hormone therapy	Endometrial evaluation should be considered when irregular bleeding persists for more than 6 months after initiating therapy		

BMD, bone mineral density.

The main indication for MHT is relief of menopausal symptoms. Many individuals have no difficulty abruptly stopping MHT; others develop vasomotor symptoms after discontinuation. Although these symptoms may be mild and resolve over a few months, in some the symptoms are severe and intolerable. There is no evidence that gradual discontinuation of MHT reduces the recurrence of hot flashes compared with sudden discontinuation.[6]

CONCLUSION

Menopause is a natural life event—not a disease. Therefore, the decision to use MHT must be individualized based on the severity of menopausal symptoms and the risk for cardiovascular disease, breast cancer, thromboembolism, and osteoporotic fracture (Table 102-9).

TABLE 102-9

Evidence-Based Hormone Therapy Guidelines for Menopausal Symptom Management

Recommendation	Recommendation Level
In the absence of contraindications, estrogen-based postmenopausal hormone therapy should be used for treatment of moderate-to-severe vasomotor symptoms	Level 1
Systemic or vaginal estrogen therapy may be used for treatment of urogenital symptoms and vaginal atrophy. However, if a patient is only experiencing bothersome GSM, low-dose vaginal estrogen therapy is recommended as first-line therapy before systemic therapy	Level 1
The type of MHT, dose, formulation, route of administration, and duration of use should be carefully considered to meet individual treatment goals for a patient. Periodic reassessment of therapy should consider changes in a individual's health, and ongoing risks and benefits of the current therapy strategy	Level 3
Postmenopausal individuals taking estrogen-based therapy should be informed about potential risks. Benefits likely outweigh risks of initiating MHT for symptomatic individuals younger than 60 years of age or within 10 years of menopause onset	Level 1
Studies demonstrate varying risks for estrogen-only therapy and estrogen and progestin therapy (eg, breast cancer risk)	Level 2
Appropriate counseling and a decision regarding duration of MHT use includes assessment of individual risk (personal and familial) for hormone sensitive cancer, osteoporosis, stroke, venous thromboembolism, and coronary heart disease	Level 3
Endometrial protection is required for individuals with an intact uterus using systemic estrogen therapy. An adequate dose and duration of progestogen or combined estrogen and progestogen or CEE with bazedoxifene is recommended to avoid endometrial hyperplasia	Level 1
Progestogen therapy is not recommended with use of low-dose (local) vaginal estrogen therapy.	Level 1
Lower doses or switching to transdermal delivery of hormone therapy may be considered as a individual ages or develops hypertriglyceridemia	Level 3
Compounded bioidentical hormone therapy is not recommended due to safety concerns regarding dosing, lack of studies demonstrating safety and efficacy	Level 1

CEE, conjugated equine estrogen; GSM, Genitourinary Syndrome of Menopause; MHT, menopausal hormone therapy.

North American Menopause Society's Level of Recommendation: Level 1, based on good and consistent scientific evidence; Level 2, based on limited or inconsistent scientific evidence; Level 3, based primarily on consensus and expert opinion.

Data from Ref. 6.

The WHI trial reported increased risk of cardiovascular disease, breast cancer, stroke, and thromboembolic disease among participants using continuous combined therapy with CEE plus MPA compared with placebo. In the estrogen-alone arm of the study, CEE had no effect on cardiovascular disease or breast cancer risk compared to placebo, but an increased risk of stroke and thromboembolic disease was noted in those who received estrogen. The WHI trial also demonstrated that quality of life and cognition were no better in the group receiving MHT than in the placebo group, and that MHT increases dementia risk in participants aged 65 years or older. Recent studies suggest dose, duration, and timing (early or late menopause) of therapy may alter the benefit-risk profile and should be considered for individual patients.

In the absence of contraindications, MHT is the most effective treatment for managing postmenopausal symptoms, such as hot flashes, night sweats, and vaginal dryness. For many individuals, the benefits of short-term use of MHT for the relief of menopausal symptoms, far outweighs any risks. For symptoms of genital atrophy alone, the use of local, nonsystemic estrogen, nonhormonal lubricants and moisturizers, or ospemifene should be considered.

Long-term use of MHT cannot be recommended routinely for osteoporosis prevention given the availability of alternative therapies, such as bisphosphonates. For long-term MHT use, the potential harm (cardiovascular disease, breast cancer, and thromboembolism) outweighs the potential benefits. MHT should not be used for prevention of CHD. Individuals with cardiovascular risk factors (eg, hypertension and lipid abnormalities) can benefit from reduction of these risk factors through interventions such as weight loss, lipid-lowering therapy, and physical activity.

ABBREVIATIONS

AUB	abnormal uterine bleeding
AMH	anti-Mullerian hormone
BMD	bone mineral density
CBHT	compounded bioidentical hormone therapy
CEE	conjugated equine estrogens
CIMT	carotid intima-media thickness
CHD	coronary heart disease
FMP	final menstrual period
FSH	follicle-stimulating hormone
GI	gastrointestinal
GnRH	gonadotropin-releasing hormone
GSM	genitourinary syndrome of menopause
HDL	high-density lipoprotein
HR	hazard ratio
LDL	low-density lipoprotein
LH	luteinizing hormone
MHT	menopausal hormone therapy
MPA	medroxyprogesterone acetate

NETA	norethindrone acetate
o-CEE	oral conjugated equine estrogens

SELF-ASSESSMENT QUESTIONS

1. The most effective treatment to alleviate postmenopausal vasomotor symptoms (hot flashes and night sweats) is

   A. Estrogen therapy.

   B. Selective estrogen-receptor modulators (SERMs).

   C. Testosterone therapy.

   D. Clonidine.

2. Which of the following CYP450 isoenzymes metabolizes both estrogen and medroxyprogesterone?

   A. 3A4

   B. 1A2

   C. 2D6

   D. All of the above

3. Continued vasomotor symptoms in a 52-year-old postmenopausal individual with a history of hysterectomy receiving 0.3 mg of oral conjugated equine estrogens can best be managed by:

   A. Changing to a SERM

   B. Changing to gabapentin

   C. Increasing the daily estrogen dose

   D. Decreasing the daily estrogen dose

4. A 54-year-old postmenopausal individual is complaining of vaginal dryness, itching, and pain with intercourse. They have not had any other problems associated with menopause and have an intact uterus. Which of the following recommendations is the best treatment option that balances risks and benefits for the management of this patient's symptoms?

   A. Oral conjugated estrogen + medroxyprogesterone acetate

   B. Transdermal estradiol + micronized oral progesterone

   C. Intravaginal estrogen cream + oral progestogen

   D. Intravaginal estrogen cream

5. Conjugated equine estrogen therapy alone has demonstrated to significantly **increase** the risk of:

   A. Coronary heart disease

   B. Stroke

   C. Colorectal cancer

   D. Breast cancer

6. Which of the following agents would be the best option to treat moderate hot flashes in a 55-year-old patient with history of breast cancer?

   A. Ospemifene

   B. Estrogen

   C. Paroxetine

   D. Progestogen

7. What is the first-line therapy for a 58-year-old postmenopausal patient suffering from mild genitourinary syndrome of menopause?

   A. Intravaginal moisturizer and lubricants

   B. Intravaginal estrogen cream

   C. Paroxetine

   D. Clonidine

8. A 52-year-old individual had a hysterectomy 6 months ago and is seeking treatment for vasomotor symptoms. There is no significant family history.

Based on the findings from the Women's Health Initiative (WHI) extended-post intervention study, what would be the most appropriate information to provide the patient regarding menopause hormone therapy (MHT):

A. Do not initiate hormone therapy now because individuals younger than 60 years have increased risk of coronary heart disease and stroke and have the least favorable benefit-risk profile with MHT

B. Initiate hormone therapy now because individuals younger than 60 years have not shown an increased risk of coronary heart disease and have most favorable benefit-risk profile with MHT

C. Initiate MHT later because individuals older than 60 years will be within the "window of opportunity" to reduce risk of breast cancer

D. Initiate hormone therapy later because individuals older than 60 years will be within the "window of opportunity" to reduce risk of coronary heart diseases

9. Long-term MHT can be routinely prescribed for which of the following conditions?

A. Dementia unresponsive to other therapies

B. Coronary heart disease

C. Diabetes

D. None of the above

10. Which of the following intravaginal estrogens is also approved for treatment of vasomotor symptoms?

A. Estring (estradiol vaginal ring)

B. Femring (estradiol vaginal ring)

C. Vagifem (estradiol vaginal tablet)

D. Imvexxy (estradiol vaginal insert)

11. A 47-year-old postmenopausal individual with an intact uterus reports experiencing bothersome vasomotor symptoms. There is a history of gall bladder disease. Which of the following is the best treatment option for management of symptoms?

A. Transdermal estrogen

B. Transdermal estrogen with micronized progesterone

C. Oral conjugated equine estrogen

D. Oral conjugated equine estrogen with micronized progesterone

12. Which of the following is most effective for the treatment of severe hot flashes in a 54-year-old healthy menopausal individual?

A. Estrogen and progestogen therapy

B. Black cohosh

C. Bazedoxifene

D. Paroxetine

13. MJ is a healthy 53-year-old female. She reports her last menses was 9 months ago. MJ is likely experiencing?

A. Menopause

B. Perimenopause

C. Postmenopause

D. Early onset menopause

14. A 51-year-old individual is experiencing severe vasomotor symptoms. The past medical history is significant for hysterectomy. Which of the following is the best treatment options to alleviate vasomotor symptoms?

    A. Black cohosh

    B. Systemic estrogen therapy

    C. Compounded bioidentical hormone therapy

    D. Transdermal estrogen with progestogen therapy

15. A 54-year-old female with a history of deep vein thrombosis, dyslipidemia, and depression is seeking treatment for bothersome vasomotor symptoms. Which of the following is the best treatment options to alleviate vasomotor symptoms?

    A. Black cohosh

    B. Medroxyprogesterone

    C. Duavee (conjugated estrogen with bazedoxifene)

    D. Paroxetine

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Estrogen therapy remains the most effective treatment for moderate and severe vasomotor symptoms, impaired sleep quality, and vulvovaginal symptoms of menopause (see Table 102-3).

2. **A.** CYP 3A4 metabolizes both estrogen and medroxyprogesterone.

3. **C.** This individual is currently taking low-dose of estrogen (0.3-mg conjugated equine estrogen daily) that is insufficient for managing vasomotor symptoms. Increasing the dose of estrogen will provide additional symptom relief (see Table 102-9).

4. **D.** This individual is experiencing isolated genitourinary syndrome of menopause. Local low-dose estrogen therapy is the preferred treatment of localized symptoms while minimizing systemic medication adverse effects. In women with an intact uterus, use of local low-dose estrogen does not require progestogen for endometrial protection as it does not increase risk of endometrial hyperplasia, however, appropriate monitoring is still warranted in all patients on hormone therapy (see Table 102-9).

5. **B.** Conjugated equine estrogen therapy alone decreases the risk of breast cancer, shows no evidence in increasing CHD events but significantly increases the risk of stroke. Estrogen monotherapy does not affect the colorectal cancer incidence (see Table 102-3).

6. **C.** Paroxetine, a nonhormone therapy, is the best option out of the provided choices for management of vasomotor symptoms in symptomatic individuals with history of breast cancer. Estrogen and progestin therapy are contraindicated in individuals with breast cancer. Ospemifene has not been adequately studied in women with breast cancer and should be avoided per current FDA-approved product labeling (see the "Other Treatments for Menopause-Related Symptoms" section).

7. **A.** The first-line therapy for mild vulvovaginal symptoms are vaginal lubricants and moisturizers (see the "Menopausal Hormone Therapy for Vasomotor and Genitourinary Syndrome Symptoms" section and Fig. 102-1).

8. **B.** Individuals under age 60 years and within 10 years of menopause have most favorable risk-benefit ratio for initiation of MHT and the risk of CHD

increases with age. Thus, the data show that the "window of opportunity" to initiate MHT is for individuals younger than 60 years (not older than 60 years) as there is no evidence of increased CHD events in this age group. Existing data did not find timing or age factor for breast cancer risks (see the "Cardiovascular Disease" section).

9. **D.** There is a lack of evidence to support the use of MHT for any of the listed conditions.
10. **B.** While all intravaginal estrogen products alleviate genitourinary syndrome of menopause, Femring is the only product that provides adequate systemic estrogen concentration and is also indicated for treatment of vasomotor symptoms. The other options provide low-dose vaginal estrogen therapy for the treatment of genitourinary syndrome of menopause (see the "Menopausal Hormone Therapy for Vasomotor and Genitourinary Syndrome Symptoms" section).
11. **B**. Transdermal estrogen is the preferred alternative for individuals at high risk for cholelithiasis. This patient has an intact uterus and therefore should also receive a progestogen to decrease the risk of endometrial hyperplasia. Micronized progesterone is preferred because less-adverse effects with lower risk of VTE and possibly stroke and coronary artery disease (see the "Other Routes of Estrogen Administration" section).
12. **A**. Hormone therapy remains the most-effective treatment for vasomotor symptoms. Individuals younger than 60 years and within 10 years of menopause have most favorable risk-benefit ratio for initiation of hormone therapy. Black cohosh is not supported by sufficient evidence for treatment of vasomotor symptoms. Bazedoxifene alone, without estrogen therapy, is not sufficient to alleviate vasomotor symptoms. Paroxetine may be considered as an alternative if patient wishes to have a nonhormone therapy, but it is not as effective for alleviating vasomotor symptoms as hormone therapy.
13. **B**. MJ's presentation at the age of 53 years is occurring later than the average age of menopause in the United States, which is 51 years. Menstrual irregularity or absence is indicative of the perimenopausal period at this age. Menopause is defined retrospectively after 12 months of amenorrhea. Postmenopause is defined as the years after the final menstrual period (see the "Introduction" section).
14. **B**. Treatment of severe vasomotor symptoms will require systemic therapy. Estrogen is the most effective therapy for vasomotor symptoms. Use of compounded bioidentical hormone therapy is not recommended due to paucity of evidence regarding the efficacy, safety, and pharmaceutical quality of these products. An individual without a uterus would not require progestogen therapy to protect against endometrial hyperplasia. Use of black cohosh is not supported by sufficient evidence for treatment of vasomotor symptoms (see the "Compounded Bioidentical Hormone Therapy" and "Other Complementary and Alternative Options" sections).
15. **D**. Black cohosh is not supported by sufficient evidence for treatment of vasomotor symptoms or depression. Use of hormone therapy (Duavee) is not recommended in patient with history of venous thromboembolism. Medroxyprogesterone is not as effective for treatment of vasomotor symptoms. Paroxetine is approved for both vasomotor symptoms and depression and is recommended for patients as a first-line therapy for individuals who have contraindications to estrogen therapy (see the "Other Complementary and Alternative Options" and "Other Treatments for Menopause-Related Symptoms" sections).

Chapter 103: Erectile Dysfunction

Mary Lee; Roohollah Sharifi

KEY CONCEPTS

KEY CONCEPTS

① The incidence of erectile dysfunction is low in men younger than 40 years of age. The incidence increases as men age likely as a result of concurrent medical conditions that impair the vascular, neurologic, psychogenic, and hormonal systems necessary for a normal penile erection.

② Many commonly used drugs have sympatholytic, anticholinergic, sedative, or antiandrogenic effects that may exacerbate or contribute to the development of erectile dysfunction. Clinicians should be familiar with these agents and be prepared to adjust drug regimens to minimize adverse effects of these drugs on a patient's erectile function.

③ The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse the underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, and chronic ethanol abuse, should be addressed and minimized.

④ Specific treatments for erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, psychotherapy, and surgery. Of these, phosphodiesterase type 5 inhibitors are the medications of first choice.

⑤ The ideal treatment of erectile dysfunction should have a fast onset, be effective, be convenient to administer, be cost -effective, have a low incidence of serious adverse effects, and be free of serious drug interactions.

⑥ Specific treatment is first initiated with the least invasive modality, including VEDs or oral phosphodiesterase type 5 inhibitors, followed by intracavernosal injections or intraurethral inserts, and finally by surgical insertion of a penile prosthesis.

⑦ Vacuum erection devices can have a slow onset of action (up to 20 minutes) during initial use and are not discreet; therefore, they are most effective for a couple in a stable relationship.

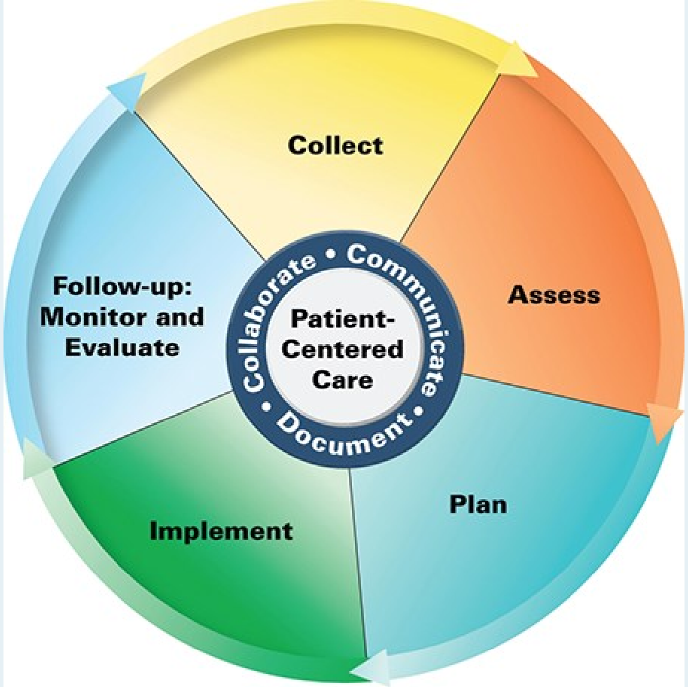
⑧ Although phosphodiesterase type 5 inhibitors are convenient and effective regardless of the etiology of erectile dysfunction, they fail in 30% to 40% of patients. Also, phosphodiesterase type 5 inhibitors are contraindicated in patients taking any dosage formulation of nitrate.

⑨ Testosterone supplementation should be reserved for symptomatic patients with primary, secondary, or mixed hypogonadism who have erectile dysfunction. Testosterone supplementation should not be used by patients with erectile dysfunction who have normal serum testosterone levels.

⑩ Although intracavernosal injections and intraurethral pellets of alprostadil are effective and independent of the etiology of erectile dysfunction, they fail in up to one-third of patients. To self-administer medication by these routes, patients require training to minimize administration-related adverse effects.

PATIENT CARE PROCESS

Patient Care Process for the Management of Erectile Dysfunction



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, race)
- Patient history (past medical history, marital/partner status, family history, social—sexual history, situations in which erectile dysfunction occurs, tobacco, recreational drug, or alcohol use, and medication history)
- Current psychologic status (emotional stressors, depression, performance anxiety) (see "Clinical Presentation" box)
- Objective data (see "Diagnosis" section)
    - BP, heart rate (HR), height, weight, and BMI
    - Physical examination to rule out hypogonadism and prostate dysfunction
    - Labs (eg, blood/serum glucose, lipids, testosterone)
    - Cardiovascular risk assessment, if indicated (see the "Diagnosis" section and Table 103-3)
- Administer International Index of Erectile Function screening questionnaire if feasible (see the "Diagnosis" section)
- Current and past medications, including prescription and nonprescription medications, or nonpharmacologic interventions for erectile dysfunction (see Table 103-4)
- If a patient is not responding to a phosphodiesterase type 5 inhibitor, details on how and when a patient is using the medication (see the "Efficacy" subsection under "Phosphodiesterase Type 5 Inhibitor" section)

Assess

- Patient and partner's pattern and frequency of sexual intercourse, their goals for treatment and expectations regarding therapy and its costs
- Patient's physical ability to engage in sexual intercourse
- Presence of conditions that are contraindications to sexual intercourse and to phosphodiesterase type 5 inhibitors (Table 103-3)
- Current use of medications contributing to erectile dysfunction (see Table 103-2)

Plan*

- Individualize treatment selection based on the patient's preferences for and perception of the effectiveness of various treatment options, out-of-pocket costs for treatment, and potential adverse effects; patients generally prefer a discreet treatment not obvious to sexual partners and not requiring careful attention to administration timing relative to sexual activity.
- Optimize treatment for underlying causes of erectile dysfunction (eg, hypertension, coronary artery disease, dyslipidemia, diabetes mellitus, smoking, chronic ethanol abuse)
- Discontinue medications contributing to erectile dysfunction when possible (Table 103-2)
- Treat hypogonadism when present
- Initiate counseling or psychotherapy for psychogenic causes of erectile dysfunction
- Drug therapy regimen including specific agent(s), dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Tables 103-4 and 103-5 and Figs. 103-2, 103-3, 103-5, and 103-6); consider the presence of concomitant diseases treatable with agents for erectile dysfunction (eg, daily tadalafil in men who also have benign prostatic hypertrophy)
- Nonpharmacologic or surgical intervention when medications are contraindicated or are not effective (see Figs. 103-2 and 103-3)
- Patient reeducation to salvage patient nonresponders to phosphodiesterase type 5 inhibitor, if appropriate (see "Efficacy" subsection under "Phosphodiesterase Type 5 Inhibitor" section)
- Monitoring parameters including efficacy (eg, BP, cardiovascular events, kidney health), safety (medication-specific adverse effects), and time frame (see Table 103-6)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy)
- Referrals to other providers when appropriate (eg, physician, urologist)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Schedule follow-up for several weeks after therapy initiation

Follow-up: Monitor and Evaluate

- Patient satisfaction with quality and quantity of penile erections
- Presence of adverse effects
- Adjust medication doses or switch to alternative agents as clinically indicated
- Consider alternative devices, drugs, combinations of drugs, or surgical intervention in patients who fail treatment with a single approach

*Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Many medications may cause or worsen erectile dysfunction. Based on the physiology of a normal erection, create a table in which you identify various classes of medications that interfere with the hormonal, vascular, neurologic, or psychogenic factors that are essential for a normal penile erection. In a separate column, identify medications that are most likely to interfere with those physiologic factors and are likely to cause erectile dysfunction.

INTRODUCTION

The National Institutes of Health Consensus Development Panel on Impotence[1] defines erectile dysfunction as the persistent or recurrent failure to achieve or maintain a penile erection to allow for satisfactory sexual intercourse. A persistent failure generally refers to erectile dysfunction for a minimum of 3 months. Patients may refer to the condition as impotence. Erectile dysfunction must be distinguished from disorders of libido or ejaculation, and of infertility, all of which are caused by different pathophysiologic mechanisms and are treated with alternative agents (Table 103-1). A patient may have one or more disorders of sexual and reproductive function. For example, an older man with primary hypogonadism could have both decreased libido and erectile dysfunction. Diagnosing the type of sexual disorders in a patient is key to initiating the most appropriate treatment.

Editors' note: In this and other chapters in Pharmacotherapy*, references to biologic gender (as assigned at birth) are used based on prior literature being discussed or anatomical or physiologic differences. We recognize that not all individuals identify with their gender at birth, and to the degree possible when discussing therapeutics, we avoid the use of references to gender. Use of gender in this chapter refers to the language used in prior studies, published guidelines, and other recommendations for diagnosis and treatment based on biological gender and does not necessarily reflect an individual's gender identity.*

TABLE 103-1

Types of Sexual Dysfunction in Men

Type of Dysfunction	Definition
Decreased libido	Decreased sexual drive or desire
Increased libido	Inappropriate and excessive sexual drive or desire
Erectile dysfunction (impotence)	Failure to achieve a penile erection suitable for satisfactory sexual intercourse
Delayed ejaculation/anejaculation	Commonly referred to as "dry sex"; ejaculation is delayed or absent
Retrograde ejaculation	Ejaculate passes retrograde into the bladder, instead of toward the anterior urethra (antegrade) and out of the penis
Infertility	Sperm are insufficient in number, have abnormal morphology, or have inadequate motility, and fail to fertilize the ovum

EPIDEMIOLOGY

① The incidence of erectile dysfunction is low in men younger than 40 years but increases as men ages. The Massachusetts Male Aging Study, a cross-sectional survey of a random sample of 1,290 men in the Boston area, was conducted during the period from 1987 to 1989. The study reported an overall prevalence of 52% for any degree of erectile dysfunction in men aged 40 to 70 years, with an age-related increase in incidence ranging from 12.4 cases per 1,000 men per year in men aged 40 to 49 years, up to 46.4 cases per 1,000 men per year in men aged 60 to 69 years.[2] In men older than 70 years, the prevalence of erectile dysfunction increases and has been reported to be as high as 80%, depending on the population studied.[2] In the Health Professional Follow-Up Study of more than 31,000 male health professionals aged 53 to 90 years, the prevalence of erectile dysfunction was 33%.[3] Interestingly, although the prevalence of erectile dysfunction increases with patient age, many patients fail to seek medical treatment. This may be due to a decrease in sexual activity as males age.

Erectile dysfunction is sometimes assumed to be a symptom of the aging process in men. However, more likely it results from concurrent medical conditions of the patient (eg, hypertension, arteriosclerosis, hyperlipidemia, diabetes mellitus, metabolic syndrome, or psychiatric disorders) or from medications that patients may be taking for these diseases.[1,2] For example, up to 50% of patients with diabetes mellitus develop erectile dysfunction, and medications such as diuretics are associated with a high incidence of erectile dysfunction.

PHYSIOLOGY OF A NORMAL PENILE ERECTION

A normal penile erection requires full functioning of several physiologic systems: vascular, nervous, and hormonal. The patient also must be psychologically receptive to sexual stimuli.

Vascular System

The penis comprises two corpora cavernosa on the dorsal side and one corpus spongiosum on the ventral side. The corpus spongiosum surrounds the urethra and forms the glans penis. The corpora are composed of multiple interconnected sinuses, which can fill with blood to produce an erection. The corpora cavernosa are encased by the tunica albuginea, a fibrous tissue membrane, which has limited distensibility. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases, and blood fills the sinusoids within the corpora. Blood traps in the corpora as the outflow of the subtunical veins are compressed against the tunica albuginea. This prolongs the erection (Fig. 103-1).

FIGURE 103-1

Microanatomy of and vascular changes in the penis in flaccid and erect states. (*Reprinted, with permission, from Walsh PC, ed. Campbell's Urology, 8th ed. Philadelphia, PA: WB Saunders; 2002:1595, 1697. Copyright © 2002 from Elsevier.*)

Arterial flow into the corpora is enhanced by acetylcholine-mediated vasodilation. Acetylcholine indirectly enhances arterial flow to the corpora and increases sinusoidal filling of the corporal tissue. That is, acetylcholine is a co-neurotransmitter, which works along with other nonpeptidergic intracellular neurotransmitters—including cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), or vasoactive intestinal polypeptide—to produce vasodilation. In effect, cGMP and cAMP are secondary messengers that direct desired effects in target tissues.

Specifically, acetylcholine produces an erection probably through two different pathways. Through one pathway, in the presence of sexual stimulation to genital tissue, acetylcholine enhances the production of nitric oxide by endothelial cells and nonadrenergic–noncholinergic neurons. Nitric oxide enhances the activity of guanylate cyclase, which increases the conversion of cyclic guanosine triphosphate to cGMP. cGMP activates a cGMP-dependent kinase, which decreases intracellular calcium concentrations in smooth muscle cells of penile arteries and cavernosal sinuses. As a result, smooth muscle relaxation occurs, which enhances arterial blood flow to and blood filling of the corpora.[4] An erection results.

In an alternative pathway, acetylcholine or prostaglandin E enhances the activity of adenyl cyclase, which increases the conversion of cyclic adenosine triphosphate to cAMP, a potent muscle relaxant. Similar to cGMP, cAMP decreases intracellular calcium concentrations to produce smooth muscle relaxation in cells of the arteries and cavernosal sinuses. Arterial blood flow to and blood filling of the corpora are enhanced, and a penile erection results.

Nervous System and Psychogenic Stimuli

Some erections are mediated by a sacral nerve reflex arc (eg, erections can occur while the patient is sleeping). However, in the conscious patient, sensory sexual stimulation mediates erections via the central nervous system (CNS). That is, when a patient sees an attractive partner, hears sweet words, smells a particular scent, or tastes or touches a pleasant object, these situations can result in an erection. In this case, the patient's brain processes this information, and the nervous impulse is carried down the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora, resulting in an erection.

The medial preoptic area of the hypothalamus is thought to be that portion of the brain responsible for integrating external stimuli. Here, dopamine exerts a proerectogenic effect, whereas alpha$_2$-adrenergic stimulation causes the penis to become and/or remain flaccid. After moving down the spinal cord, stimulatory nerve impulses travel to the penis by efferent peripheral nerves, including inhibitory sympathetic neurons (T_{11}-L_2), proerectogenic parasympathetic neurons (S_2-S_4), and proerectogenic somatic neurons (S_2-S_4).

In short, acetylcholine produces an erection by working along with other co-neurotransmitters, including cGMP and cAMP. Thus, an erection is mediated neurologically, maintained by arterial blood filling of the corpora, and sustained by occlusion of venous outflow from the corpora.

Detumescence, or the progression of an erect penis to a flaccid state, results from the actions of norepinephrine, which contracts vascular smooth muscle to decrease arterial inflow to the corpora and contracts sinusoidal tissue in the corpora. As a result, venous outflow from the corpora increases.

Hormonal System

Testosterone is principally produced by the testes at a daily rate of 4 to 8 mg and a normal physiologic serum concentration is 300 to 1,100 ng/dL (10.4-38.2 nmol/L). Production follows a circadian pattern with the highest blood levels in the morning and lowest levels in the evening. Physiologically active (free) testosterone comprises only 2% of circulating blood levels. About 44% of testosterone in the bloodstream is tightly bound to sex hormone-binding globulin and is inactive. Approximately 50% is reversibly bound to albumin and 4% is reversibly bound to corticosteroid-binding globulin; both of these portions of testosterone are in equilibrium with the 2% of testosterone that is not bound. Thus, the bioavailable portion of testosterone is normally 56% and comprises testosterone bound to albumin and corticosteroid-binding globulin, and the unbound or free portion.[5] However, the bioavailable percentage of testosterone can vary considerably with changes in sex hormone-binding globulin. Sex hormone-binding globulin increases with aging, hyperthyroidism, human immunodeficiency virus disease, and hepatic cirrhosis and decreases with obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, and corticosteroid use.[5]

Testosterone stimulates libido (sexual drive) and increases muscle mass in males. In addition, androgen receptors have been identified in the penile arterial endothelium and are thought to increase cavernosal levels of nitric oxide and cGMP, thereby enhancing vascular processes essential for a penile erection. In addition, androgens may enhance phosphodiesterase type 5 activity and may improve cavernosal nerve function.

ETIOLOGY/PATHOPHYSIOLOGY

Erectile dysfunction can result from any single abnormality or combination of abnormalities of the four systems necessary for a normal penile erection. Vascular, neurologic, or hormonal etiologies of erectile dysfunction are collectively referred to as *organic erectile dysfunction*. Approximately 80% of elderly patients with erectile dysfunction have the organic type. Patients who do not respond to psychogenic stimuli and have no organic cause for dysfunction have *psychogenic erectile dysfunction*.[6]

Diseases that compromise vascular flow to the corpora cavernosum (eg, peripheral vascular disease, arteriosclerosis, and essential hypertension) comprise the most common causes of organic erectile dysfunction.[7] Erectile dysfunction is increasingly recognized as a predictor of cardiovascular disease.[8] This is because penile arteries are small caliber blood vessels when compared to coronary or carotid arteries; the diameters are 1 to 2 mm, 3 to 4 mm, and 5 to 6 mm, respectively. As a result, erectile dysfunction could be one of the first signs of atherosclerosis and may predict future cardiovascular disease.[8]

In addition to decreasing arterial blood flow to the corpora cavernosa, atherosclerosis may cause erectile dysfunction by causing inflammation to or impairing the function of vascular endothelial cells. As a result, nitric oxide release is decreased. Since nitric oxide is essential for the relaxation of cavernosal sinusoidal tissue, tumescence is impaired.[8]

Neurological disorders cause 10% to 20% of all cases of organic erectile dysfunction. Diseases that impair nerve conduction to the central nervous system (eg, Parkinson's disease, epilepsy, stroke, spinal cord injury) or conditions that impair peripheral nerve conduction to the penile vasculature (eg, diabetes mellitus, alcoholic neuropathy) can cause erectile dysfunction.[9]

Patients must be in the proper mental frame of mind to be receptive to sexual stimuli. Patients who suffer from malaise, have reactive depression or performance anxiety, are sedated, or have Alzheimer's disease, hypothyroidism, or mental disorders commonly complain of erectile dysfunction. In most studies, patients with psychogenic erectile dysfunction generally exhibit a higher response rate to various interventions than do patients with organic erectile dysfunction because the former have less severe disease.

Psychogenic causes of erectile dysfunction appear to be more prevalent in men under the age of 40 years of age. Depression, performance anxiety, lack of self-confidence, or partner-related problems are contributory.[10]

Diseases associated with hypogonadism, primary, secondary, or mixed, result in subphysiologic levels of testosterone, which cause diminished sexual drive (decreased libido) and secondary erectile dysfunction. Primary hypogonadism occurs with surgical removal of the testes for the treatment of prostate or testicular cancer or with testicular injury or disease. Secondary hypogonadism may result from hypothalamic or pituitary disorders of luteinizing hormone-releasing hormone or luteinizing hormone, respectively, or elevated prolactin levels, which can be associated with pituitary tumors, or can occur in patients with chronic renal failure.

Late-onset hypogonadism refers to the physiologic changes in testosterone in aging males. The etiology of hypogonadism is mixed. In addition to decreased Leydig cell function in the testes, hypothalamic release of luteinizing-releasing hormone is reduced, the circadian pattern of luteinizing hormone release from the pituitary gland is impaired, and sex hormone-binding globulin production increases.[11] Serum testosterone levels decrease starting at age 40 years by approximately 10% per decade of life. Thus, the prevalence of late-onset hypogonadism ranges from 3.2% and 5.1% in men aged 60 to 69 years and in men aged 70 to 79 years, respectively.[11,12] Symptoms include decreased libido, gynecomastia, small testes, reduced growth of body hair and beard, decreased muscle mass, and increased body fat. Decreased libido is associated with erectile dysfunction and loss of spontaneous morning erections. In addition, patients may complain of a depressed mood and tiredness, which may also contribute to erectile dysfunction. If left untreated, patients develop anemia and osteoporosis.

However, it must be noted that the relationship between erectile dysfunction and serum testosterone levels is complicated. Patients with normal serum testosterone levels may have erectile dysfunction, and patients with subnormal serum testosterone levels may have normal sexual function.[11]

Some patients have multiple factors contributing to the development of erectile dysfunction. Consider the typical older adult with cardiovascular disease, who is a smoker and has hypertension and diabetes mellitus, which are medically treated. The pathophysiology of erectile dysfunction in this patient includes vascular, neurologic, and hormonal origins. In addition, many common antihypertensive medications may cause erectile dysfunction.[13]

Social habits of patients have been linked to erectile dysfunction. The vasoconstrictor effect of cigarette smoking may compromise blood flow to the corpora and decrease cavernosal filling. Excessive ethanol intake may lead to androgen deficiency, peripheral neuropathy, or chronic liver disease, all of which can contribute to erectile dysfunction.

② Medications may cause erectile dysfunction through similar pathophysiologic mechanisms (Table 103-2). Medications are responsible for approximately 10% to 25% of cases of erectile dysfunction. Two excellent reviews have been published.[14,15]

TABLE 103-2

Medication Classes that Can Cause Erectile Dysfunction

Drug Class	Proposed Mechanism by Which Drug Causes Erectile Dysfunction	Special Notes
Anticholinergic agents (antihistamines, antiparkinsonian agents, tricyclic antidepressants, phenothiazines)	Anticholinergic activity	• Second-generation nonsedating antihistamines (eg, loratadine, fexofenadine, or cetirizine) are associated with less erectile dysfunction than first-generation agents. • Selective serotonin reuptake inhibitor (SSRI) and multiple receptor reuptake inhibitor antidepressants cause less erectile dysfunction than tricyclic antidepressants. Of the SSRIs, paroxetine, sertraline, fluvoxamine, and fluoxetine cause erectile dysfunction more commonly than venlafaxine, nefazodone, trazodone, bupropion, duloxetine, mirtazapine, escitalopram, or vilazodone.[16] • Phenothiazines with less anticholinergic effect (eg, chlorpromazine) can be substituted in some patients if erectile dysfunction is a problem.

Dopamine antagonists (eg, metoclopramide, phenothiazines)	Inhibit prolactin inhibitory factor, thereby increasing prolactin levels	- Increased prolactin levels inhibit testicular testosterone production; depressed libido results.
Estrogens or drugs with antiandrogenic effects (eg, luteinizing hormone-releasing hormone superagonists, digoxin, spironolactone, ketoconazole, cimetidine)	Suppress testosterone-mediated stimulation of libido	- In the face of decreased libido, a secondary erectile dysfunction develops because of diminished sexual drive.[7]
CNS depressants (eg, barbiturates, narcotics, benzodiazepines, short-term use of large doses of alcohol, anticonvulsants)	Suppress perception of psychogenic stimuli	
Agents that decrease penile blood flow (eg, diuretics, peripheral β-adrenergic antagonists, or central sympatholytics [methyldopa, clonidine, guanethidine])	Reduce arteriolar flow to corpora	- Any diuretic that produces a significant decrease in intravascular volume can decrease penile arteriolar flow. - Spironolactone has estrogenic effects, and has a high potential to decrease libido and cause erectile dysfunction when used in large doses.[17] - First-generation beta blockers (eg, propranolol) or second-generation agents (eg, atenolol or metoprolol) are associated with more erectile dysfunction than newer generation agents (eg, nebivolol), which possess vasodilatory actions through blockade of alpha adrenoreceptors and release of nitric oxide.[17,18] - Safer antihypertensives include angiotensin-converting enzyme inhibitors, postsynaptic alpha$_1$-adrenergic antagonists (terazosin, doxazosin), calcium channel blockers, and angiotensin II receptor antagonists.[7,19]
Miscellaneous - Finasteride, dutasteride	Erectile dysfunction from 5-alpha reductase inhibitors is thought to result from inhibition of androgen-mediated nitric oxide production by vascular endothelial cells.[20]	- Sexual dysfunction has been reported to persist even after the 5-alpha reductase inhibitor is discontinued.[21]
Lithium carbonate	Unknown mechanism	
Gemfibrozil	Unknown mechanism	
Interferon	Unknown mechanism	
Clofibrate	Unknown mechanism	

Monoamine oxidase inhibitors (eg, phenelzine, isocarboxazid, tranylcypromine)	Unknown mechanism	
Opiates	Unknown mechanism	

SSRI, selective serotonin reuptake inhibitor.

Data from References 6,14,15.

DIAGNOSIS

With the availability in the late 1990s of effective medications for erectile dysfunction independent of the etiology, diagnostic evaluation of erectile dysfunction became streamlined. Key assessments include a description of the severity of erectile dysfunction, complete medical, psychosocial, and surgical histories, review of concurrent medications, physical examination, assessment of cardiac reserve, and selected clinical laboratory tests.[22]

To assess the severity of erectile dysfunction, the patient should be asked about the quality of sexual intercourse for the past 4 weeks to 6 months. A self-administered standardized questionnaire, such as the International Index of Erectile Function (IIEF), is often used. It is administered before initiation of any treatment and repeated at regular intervals during treatment to assess changes. The IIEF is considered a gold standard tool. It includes 15 questions about orgasmic function, libido, erectile function, intercourse satisfaction, and overall satisfaction.[22] Shorter versions of the IIEF are also used in clinical practice. For example, the IIEF-EF includes only the five or six questions that focus on erectile function. The patient responds to each question; each response is scored on a range of 1 to 5. For a six-question IIEF-EF, a score of 26 to 30 is considered normal function, 19 to 25 is mild erectile dysfunction, 13 to 18 is mild-to-moderate erectile dysfunction, 7 to 12 is moderate erectile dysfunction, and 6 or less is severe erectile dysfunction.[23] For a five-question IIEF-EF, a score of 22 to 25 is considered normal function, 17 to 21 is considered mild erectile dysfunction, 12 to 16 is mild-to-moderate erectile dysfunction, and 8 to 11 is moderate erectile dysfunction, and 1 to 7 is severe erectile dysfunction.[23]

Other commonly used questionnaires include the Sexual Health Inventory for Men, Erection Hardness Score, Erectile Dysfunction Inventory for Treatment and Satisfaction, and Treatment Satisfaction Score.[23]

A medical history should be obtained to identify concurrent medical illnesses (eg, hypertension, atherosclerosis, hyperlipidemia, diabetes mellitus, and depression) or surgical procedures (eg, perineal or pelvic) that are risk factors for or are associated with organic or psychogenic erectile dysfunction. Underlying diseases that have not responded to treatment should be addressed before specific treatment for erectile dysfunction is initiated. If the patient smokes cigarettes, drinks excessive amounts of ethanol, or uses recreational drugs, these social habits should be discontinued before specific treatment for erectile dysfunction is started.[24,25]

A complete listing of the patient’s prescription and nonprescription medications and dietary supplements should be reviewed by the clinician, who should identify any drugs that could be contributing to erectile dysfunction. If possible, causative agents should be discontinued or the dose should be reduced.

A physical examination of the patient should include a check for hypogonadism (ie, signs of gynecomastia, small testicles, and decreased beard or body hair). The penis should be evaluated for diseases associated with abnormal penile curvature (eg, Peyronie’s disease), which are associated with erectile dysfunction. Femoral and lower extremity pulses should be assessed to provide an indication of vascular supply to the genital area. Anal sphincter tone and other genital reflexes should be checked for the integrity of the nerve supply to the penis. A digital rectal examination in patients aged 50 years or older is needed to rule out benign prostatic hyperplasia, which may contribute to erectile dysfunction.

Erectile dysfunction is a potential marker for arteriosclerotic cardiovascular disease. Sexual intercourse and orgasm require a cardiac work equivalent to that needed to vigorously climb two flights of stairs or to walk approximately 1.5 km. In addition, erectogenic drugs may stress the heart.[26] For this reason, a patient's cardiac reserve should be assessed before initiating the treatment for erectile dysfunction. According to the Princeton Consensus Conference guideline, the clinician should take a careful cardiovascular disease history and check for signs and symptoms of cardiovascular disease. Drug treatment for erectile dysfunction is recommended only in patients at low risk of cardiovascular events. Drug treatment should be avoided in patients at high risk of cardiovascular events. For patients at intermediate risk, treadmill testing is indicated; results will stratify patients into low- and high-risk groups, which should be managed accordingly. The risk assessment is described in Table 103-3 and detailed in the Third Princeton Consensus Panel recommendations.[19,26]

TABLE 103-3

Recommendations of the Third Princeton Consensus Conference for Cardiovascular Risk Stratification of Patients Being Considered for Phosphodiesterase Inhibitor Therapy

Risk Category	Description of Patient's Condition	Management Approach
Low risk	Has asymptomatic cardiovascular disease with <3 risk factors for cardiovascular disease Has well-controlled hypertension Has mild congestive heart failure (NYHA class I or II) Has mild valvular heart disease Has had a myocardial infarction >8 weeks ago	Patient can be started on phosphodiesterase inhibitor
Intermediate risk	Has ≥3 risk factors for cardiovascular disease Has mild or moderate, stable angina Had a recent myocardial infarction or stroke within the past 2-8 weeks Has moderate congestive heart failure (NYHA class III) History of stroke, transient ischemic attack, or peripheral artery disease	Patient should undergo a complete cardiovascular workup and treadmill stress test to determine tolerance to increased myocardial energy consumption associated with increased sexual activity. Then, reclassify in the low- or high-risk category
High risk	Has unstable or refractory angina, despite treatment Has uncontrolled hypertension Has severe congestive heart failure (NYHA class IV) Has had a recent myocardial infarction or stroke within the past 2 weeks Has moderate or severe valvular heart disease Has high-risk cardiac arrhythmias Has obstructive hypertrophic cardiomyopathy	Phosphodiesterase inhibitor is contraindicated; sexual intercourse should be deferred

NYHA, New York Heart Association.

Data from References 19,26.

Selected laboratory tests should be obtained to identify the presence of underlying diseases that could cause erectile dysfunction. These include a fasting serum blood glucose and lipid profile. Serum testosterone levels should be checked in patients older than 50 years and in younger patients who complain of decreased libido and erectile dysfunction. At least two early morning serum testosterone levels on different days, approximately 4 weeks apart, are needed to confirm the presence of hypogonadism. Within the normal physiologic range for serum total testosterone concentration, sexual drive is usually normal. Because of variability in circulating levels of sex hormone-binding globulin and the lack of precision of available assays, a patient's serum concentration of testosterone should always be interpreted in the context of the patient's symptoms and physical exam findings.[5]

The range of serum total testosterone levels that defines hypogonadism varies among various expert organizations. The Food and Drug Administration (FDA) defines hypogonadism when the serum testosterone concentration is less than 300 ng/dL (10.4 nmol/L) in an adult man, but treatment is indicated only in patients who have symptomatic hypogonadism.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Erectile Dysfunction

General

Men with erectile dysfunction are affected emotionally in different ways, and may present with

- Depression.
- Performance anxiety.
- Marital difficulties and avoidance of sexual intimacy (patients are often brought to a physician by their partners).
- Nonadherence to medications that the patient believes are causing erectile dysfunction.

Symptoms

- Erectile dysfunction or inability to have sexual intercourse, which may or may not be associated with decreased libido and ejaculatory disorders.

Signs

- IIEF questionnaire results are consistent with low satisfaction with the quality of erectile function.
- Medical history may identify concurrent medical illnesses or past surgical procedures that interfere with good vascular flow to the penis, damaged nerve function to the corpora, or mental disorders associated with decreased reception of sexual stimuli.
- Medication history may reveal prescription or nonprescription medications that could cause or contribute to erectile dysfunction.
- Physical examination may reveal signs of hypogonadism (eg, gynecomastia, small testicles, decreased body hair or beard, and decreased muscle mass), which may contribute to erectile dysfunction. The patient may have an abnormally curved penis when erect, decreased pulses in the pelvic region (suggesting impaired vascular flow to the penis), or decreased anal sphincter tone (suggesting impaired nerve function to the corpora). Men older than 50 years should undergo a digital rectal examination to determine whether an enlarged prostate is contributing to the patient's erectile dysfunction.

Assessments

- Conduct IIEF-EF to assess the severity of the patient's erectile dysfunction.[22,23]
- Complete a thorough medical history and check for any psychologic issues (eg, personal relationship issues), social habits (eg, smoking), that

might be contributing to erectile dysfunction.[22,24]

- Assess cardiac reserve based on the patient's medical history, signs and symptoms of cardiovascular disease, and treadmill testing, if indicated.

Laboratory Tests

- If the patient has signs of hypogonadism and complains of decreased libido, a serum testosterone concentration may be below the normal range, which would be consistent with a hormonal cause of erectile dysfunction. A low serum testosterone level should always be confirmed with a repeat blood level.
- If the patient has an enlarged prostate noted on digital rectal examination, blood prostate-specific antigen should be measured, especially if the patient is aged 50 or older. If elevated, the patient should be evaluated for a prostate disorder, which could contribute to erectile dysfunction.
- For patients with a history of cardiovascular disease, a fasting glucose and lipid profile is recommended to determine if treatment for risk factors for erectile dysfunction needs to be optimized.

TREATMENT

Desired Outcomes

The goal of treatment is to improve the quantity and quality of penile erections suitable for intercourse and considered satisfactory by the patient and his partner. Simple as this may sound, healthcare providers must ensure that patients and their partners have reasonable expectations before any therapies are initiated. Furthermore, only patients with erectile dysfunction should be treated. Patients who have normal sexual function should not seek—or be encouraged to seek—treatment in an effort to enhance sexual function or enable increased activity. Measures of improvement proposed include a minimum increase of at least 4 points in the IIEF-EF score or achievement of a total score of at least 20.[23] In addition, treatment should be well tolerated and be of reasonable cost.

General Approach to Treatment

③ The Third Princeton Consensus Conference recommendations are a widely accepted multidisciplinary approach to managing erectile dysfunction that maps out a stepwise treatment plan.[26] Since erectile dysfunction, cardiovascular disease, and tcardiovascularheir risk factors coexist in many patients, vigorous sexual intercourse can precipitate serious cardiovascular consequences in high-risk patients. Thus, the first step in clinical management of erectile dysfunction is to identify and, if possible, reverse underlying causes. Risk factors for erectile dysfunction, including hypertension, coronary artery disease, dyslipidemia, diabetes mellitus, smoking, or chronic ethanol abuse, should be addressed and minimized.[24,26] Patients should follow a heart-healthy lifestyle, which includes aerobic exercise, weight loss to achieve a normal body mass index, low cholesterol diet, no excessive ethanol intake, and no smoking.[7,17,27–29] In some cases, these types of interventions are sufficient to restore erectile function.[2,6,16,22] However, if erectile dysfunction does not respond to these measures, specific treatment is indicated.

④ ⑤ ⑥ Specific treatments of erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, and surgery. The ideal treatment of this disorder should have a fast onset, be effective, be convenient to administer, be cost-effective, have a low incidence of serious adverse effects, and be free of serious drug interactions (Table 103-4). Generally, when choosing from among treatment approaches, those that are least invasive are selected first; more invasive therapies are reserved for patients who do not respond to first-line agents.

TABLE 103-4

Dosing Regimens for Selected Drug Treatments for Erectile Dysfunction

Drug	Brand Name*	Initial Dose	Usual Range	Special Population Dose	Other

Phosphodiesterase Inhibitor					
Sildenafil	Viagra	50 mg orally 1 hour before intercourse	25-100 mg 1 hour before intercourse. Limit to one dose per day	In patients aged 65 years and older, start with 25 mg dose. In patients with creatinine clearance less than 30 mL/min (0.5 mL/s) or severe hepatic impairment, limit starting dose to 25 mg. In patients with mild-to-moderate hepatic impairment or those taking strong CYP3A4 inhibitors (eg, itraconazole, ketoconazole, or erythromycin), consider starting with 25 mg. In patients taking protease inhibitors, limit starting dose to 25 mg.	Generic formulations are available. Titrate dose so that erection lasts no more than 1 hour. High-fat foods decrease the rate of absorption by 1 hour. Avoid taking dose with grapefruit juice. Contraindicated with nitrates by any route of administration.
Vardenafil	Levitra[a]	5-10 mg orally 1 hour before intercourse	5-20 mg 1 hour before intercourse. Limit to one dose per day	In patients aged 65 years and older, start with 5 mg Levitra. No dosage adjustment is required in patients with decreased creatinine clearance or mild hepatic impairment. In patients with moderate hepatic impairment, start with 5-mg Levitra. Use not recommended in patients with severe hepatic impairment. In patients taking strong P450 CYP3A4 inhibitors (eg, atazanavir, erythromycin, clarithromycin, ketoconazole, itraconazole), limit starting dose to 2.5 mg in a 24-hour period. In patients on ritonavir, limit dose to 2.5 mg every 72 hours. Not recommended in patients with congenital prolonged QT interval or in patients taking Type 1A or Type 3 antiarrhythmics.	Generic formulations are available. Titrate dose so that erection lasts no more than 1 hour. High-fat foods decrease the rate of absorption by 1 hour. Avoid taking the dose with grapefruit juice. Contraindicated with nitrates by any route of administration.
	Staxyn[b]	10-mg tablet to dissolve on the tongue 1 hour before intercourse	10-mg tablet to dissolve on the tongue 1 hour before intercourse. Limit to one dose per day	Dose of Staxyn requires no adjustment in patients aged 65 years or older, patients with creatinine clearance less than 30 mL/min (0.5 mL/s), or those with mild hepatic impairment. Do not use in patients with moderate or severe hepatic	Generic formulations are available. Staxyn should be taken without any liquid or food. The tablet should be placed on the tongue where it will dissolve. No up-titration of dose is recommended. Do not

				impairment or those taking moderately or highly potent P450 CYP3A4 inhibitors. Do not initiate Staxyn in patients taking *alpha*-adrenergic antagonists.	substitute Staxyn for Levitra, or vice versa.
Tadalafil	Cialis	5-10 mg orally at least 30 minutes before intercourse OR 2.5-5 mg orally once daily	10-20 mg at least 30 minutes before intercourse. Limit to one dose per day 2.5-5 mg once daily. Limit to one dose per day	Dose of tadalafil requires no dosage adjustment in patients aged 65 years or older. In patients with creatinine clearance of 30-50 mL/min (0.5-0.83 mL/s), limit starting dose to 10 mg every 48 hours; if less than 30 mL/min (0.5 mL/s), limit starting dose to 5 mg every 72 hours. In patients with mild-to-moderate hepatic impairment, limit starting dose to 10 mg every 24 hours. Do not use in patients with severe hepatic impairment. In patients taking potent P450 CYP3A4 inhibitors, limit starting dose to 10 mg every 72 hours (if using it on demand) or 2.5 mg daily (if using a continuous daily regimen).	Generic formulations are available. Titrate dose so that erection lasts not more than 1 hour. Food does not affect rate or extent of drug absorption. Avoid taking dose with grapefruit juice. Contraindicated with nitrates by any route of administration. When taken with large amounts of ethanol, tadalafil may cause orthostatic hypotension.
Avanafil	Stendra	100 mg orally 15 minutes before intercourse	50-200 mg orally 15 minutes before intercourse. Limit to one dose per day	Dosage adjustment needed in patients aged 65 years or older. In patients with creatinine clearance of 30-89 mL/min (0.5-1.49 mL/s) or those with mild-to-moderate hepatic impairment, no dosage adjustment is needed. Not recommended if creatinine clearance is less than 30 mL/min (0.5 mL/s), if the patient has severe hepatic disease, or if the patient is taking potent P450 CYP3A4 inhibitors. If the patient is	Titrate dose so that erection lasts no more than 1 hour. May be taken with or without food. Avoid taking dose with grapefruit juice. Contraindicated with nitrates by any route of administration. When taken with large amounts of ethanol, avanafil may cause orthostatic hypotension.

				taking moderate P450 CYP3A4 inhibitors (eg, erythromycin, fluconazole), the maximum recommended dose is 50 mg every 24 hours.	
Prostaglandin E_1					
Alprostadil intracavernosal injection	Caverject, Edex	2.5-mcg intracavernosally 5-10 minutes before intercourse	10-40 mcg 5-10 minutes before intercourse. Maximum recommended dose is 60 mcg. Limit to not more than one injection per day and not more than three injections per week with a 24-hour interval between doses. Give each dose over 5-10 seconds	In older adults, use the lowest effective dose. No specific dosage adjustment provided in labeling for patients with hepatic or renal impairment.	Titrate dose to achieve an erection that lasts 1 hour. Patient will require training on aseptic intracavernosal injection technique. Avoid intracavernosal injections in patients with sickle cell anemia, multiple myeloma, leukemia, severe coagulopathy, schizophrenia, poor manual dexterity, severe venous incompetence, severe cardiovascular disease, or Peyronie's disease.
Alprostadil intraurethral pellet	Muse	125-250 mcg intraurethrally 5-10 minutes before intercourse	250-1,000 mcg just before intercourse. Limit to not more than two doses per day	In older adults, use the lowest effective dose. No specific dosage adjustment provided in labeling for patients with hepatic or renal impairment.	Patient will require training on proper intraurethral administration techniques. Use applicator provided to administer medications to avoid urethral injury.
Testosterone Supplements[c]					
Methyltestosterone	Methitest	10 mg once daily	10-50 mg once daily	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	Not recommended for use due to extensive first-pass hepatic catabolism and because it is associated with hepatotoxicity. May cause fluid retention in patients with renal or hepatic disease.
Testosterone cypionate intramuscular injection	Depo-Testosterone	100-200 mg every 2-4 weeks	200-400 mg every 2-4 weeks (up to 6 weeks)	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	During the dosing interval, supraphysiologic serum concentrations of testosterone are produced

					during a portion of the dosing interval. This has been linked to mood swings and infertility.
Testosterone enanthate intramuscular injection		100-200 mg every 2-4 weeks	200-400 mg every 2-4 weeks (up to 6 weeks)	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	During the dosing interval, supraphysiologic serum concentrations of testosterone are produced during a portion of the dosing interval. This has been linked to mood swings and infertility.
Testosterone undecanoate intramuscular injection	Aveed	750 mg as a single dose	750 mg as a single dose on Day 0, Week 4, and then 750 mg every 10 weeks	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults. Contraindicated in patients with serious hepatic or renal disease.	Only available in facilities certified through a Risk Evaluation and Mitigation Strategy Program. Administer by deep intramuscular injection into gluteal muscle. Avoid intravascular injection, which can lead to pulmonary oil embolism.
Testosterone transdermal patch	Androderm	4 mg as a single dose at bedtime	2-6 mg as a single dose at bedtime. Titrate dose 2 weeks after initiating a dose. Multiple patches may be needed to achieve dose needed.	No dosage adjustment is provided in labeling for patients with renal or hepatic impairment or older adults.	When administered at bedtime, serum concentrations of testosterone in the usual circadian pattern are produced. Apply to those body sites recommended in the package labeling: upper arm, back, abdomen, and thigh. Rotate application sites every 7 days. May have to apply multiple patches at one time to achieve appropriate serum testosterone level. Avoid swimming, showering, or washing administration site for 3 hours after patch application.
Testosterone gel	AndroGel 1% (25 mg/2.5 g) Testim 1% (25	5-10 g of gel (equivalent to 50-100 mg testosterone, respectively) as a	5-10 g of gel (equivalent to 50-100 mg testosterone, respectively) as a	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	Cover application site to avoid inadvertent transfer to others. Avoid swimming, showering, or washing administration site for 2 hours after gel

	mg/2.5 g)	single dose in the morning	single dose in the morning. Titrate dose at 14-day intervals		application. Apply to those sites recommended in the product labeling. For Androgel, apply to shoulders, upper arms, or abdomen. For Testim, apply to shoulders or upper arms only. Children and women should avoid contact with unclothed or unwashed application sites. Patients should wash hands with soap and water after administration of transdermal testosterone product. For patients who have difficulty measuring the appropriate dose using tubes of gel, it is also available in premeasured dose packets or from a pump dispenser. REMS assessments must be submitted to the FDA.
	AndroGel 1.62% (20.25 mg/1.25 g)	2 pumps (equivalent to 40.5 mg testosterone) as a single dose in the morning	2-4 pumps (equivalent to 40.5-81 mg) as a single dose in the morning. Titrate dose 14-28 days after starting treatment	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	Apply to shoulders and upper arms. Avoid swimming, showering, or washing administration site for 2 hours after application. Same precautions as listed above for 1% gel. REMS assessments must be submitted to the FDA.
Testosterone transdermal spray	Fortesta 2% (10 mg/actuation)	4 sprays (equivalent to 40-mg testosterone) every morning	4-7 sprays (equivalent to 40-70 mg testosterone) every morning. Titrate dose up at 14- to 35-day intervals	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	Must prime pump by pushing on pump three times. Apply to front or inner thighs only. Cover application site to avoid inadvertent transfer to others. Avoid swimming, showering, or washing administration site for 2 hours after spray application. Children and women should avoid contact with unclothed or unwashed application sites. Patients should wash hands with soap and water after administration of transdermal testosterone

					product. REMS assessments must be submitted to the FDA.
Testosterone transdermal solution	Axiron (30 mg/actuation)	One pump spray (equivalent to 30-mg testosterone) to left or right axilla daily	One to four pump sprays (equivalent to 30-120 mg testosterone, respectively) to axilla daily. If dose is more than one pump spray, divide total dose between axillae. Titrate dose at 14- to 35-day intervals	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	Limit application to axilla. Apply antiperspirant or deodorant before Axiron. If applying multiple spray doses to an axilla, apply one spray, let dry, then apply second dose. Avoid swimming, showering, or washing administration site for 2 hours after application. REMS assessments must be submitted to the FDA.
Testosterone intranasal gel	Natesto (5.5 mg/actuation)	2 pump actuations in nostrils (equivalent to 1 pump actuation per nostril, total dose of 11 mg) three times a day	2 pump actuations in nostrils (equivalent to 1 pump actuation per nostril, total dose of 11 mg) three times a day. If serum testosterone level is not corrected with this dose, it is recommended to switch to an alternative testosterone supplement	No dosage adjustment provided in labeling for patients with renal or hepatic impairment or older adults.	Administer each dose 6 to 8 hours apart. Prime pump by inverting and depressing pump 10 times. Blow nose before application. After administration, press on nostrils and lightly massage. Do not blow nose or sniff for 1 hour after administration. Do not administer with any other intranasal product, except decongestants. Discontinue if patient has rhinitis. If patient develops severe rhinitis, temporarily switch to an alternative testosterone replacement product until rhinitis resolves. Avoid use in patients with chronic nasal conditions, sinusitis, or after nasal or sinus surgery.
Testosterone subcutaneous implant pellet	Testopel 75 mg/pellet	150-450 mg (equivalent to 2-6 pellets) as a single dose every 3-6 months	150-450 mg as a single dose every 3-6 months	No dosage adjustment recommended for renal or hepatic impairment or older adults.	Trained health professional is required to administer the dose. Use sterile implanter kit. Administration of the dose requires a forearm incision and local anesthesia to

					subcutaneously implant dose. Clinical onset is delayed for 3-4 months after initial dose. Generic formulations are available in higher strengths: 100 or 200 mg per pellet.

[*] Common brand names are included in this table. Medications may be available with other brand names or as generic formulation.

[a] Levitra brand was discontinued in April 2021. Vardenafil is available as generic formulation.

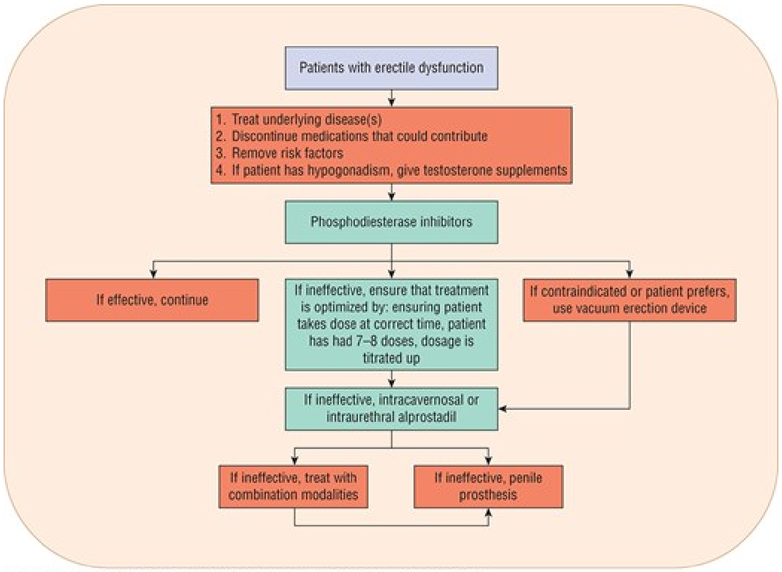
[b] Staxyn brand was discontinued in April 2021. Vardenafil is available as generic formulation.

[c] This listing includes only those testosterone supplements approved for treating hypogonadism associated with aging. Testosterone enanthate auto-injector and oral testosterone undecanoate are not included for this reason.

The British Society of Sexual Medicine,[16] 2018 American Urological Association,[22] and the Fourth International Consultation of Sexual Medicine[30] clearly identify oral phosphodiesterase type 5 inhibitors for first-line treatment. VEDs, intracavernosal injection of erectogenic agents, or intraurethral prostaglandin pellets are second-line treatments. Prescribing a particular agent for a patient should be individualized. Surgical intervention should be reserved for patients who fail to respond to first- and second-line treatments. A sample algorithm that guides the selection of treatment is shown in Fig. 103-2.

FIGURE 103-2

Algorithm for selecting treatment for erectile dysfunction.



Patients with erectile dysfunction
1. Treat underlying disease(s)
2. Discontinue medications that could contribute
3. Remove risk factors
4. If patient has hypogonadism, give testosterone supplements
Phosphodiesterase inhibitors
If effective, continue
If ineffective, ensure that treatment is optimized by: ensuring patient takes dose at correct time, patient has had 7–8 doses, dosage is titrated up
If contraindicated or patient prefers, use vacuum erection device
If ineffective, intracavernosal or intraurethral alprostadil
If ineffective, treat with combination modalities
If ineffective, penile prosthesis

Nonpharmacologic Therapy

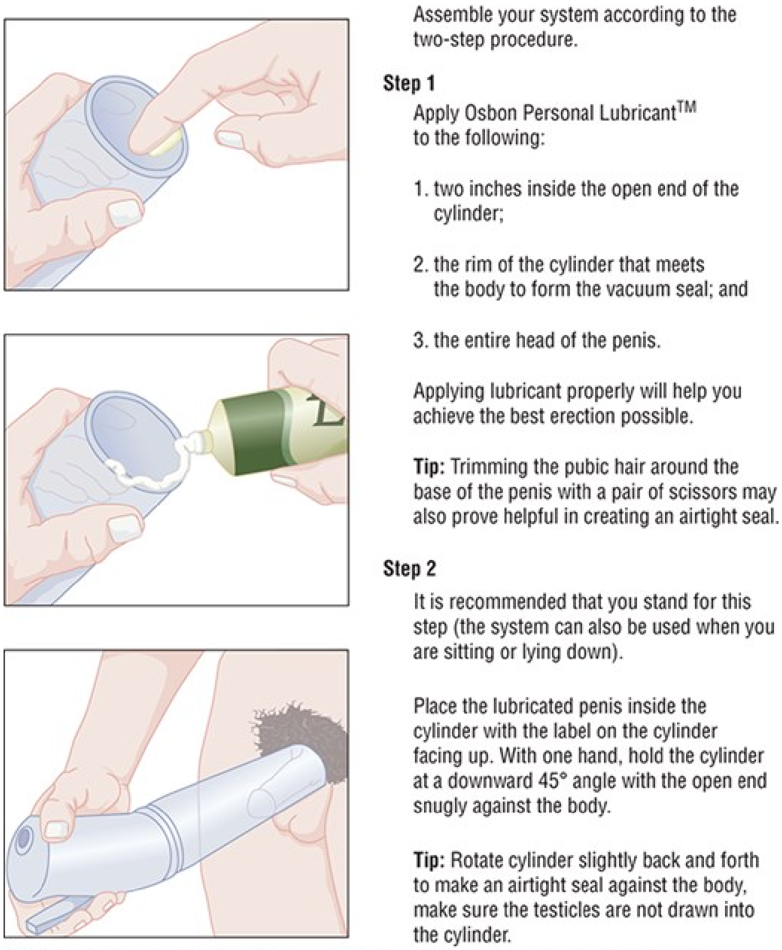
Vacuum Erection Device

A vacuum erection device (VED) is a noninvasive medical device with few contraindications to use. It is available over-the-counter. A patient makes a one-time purchase, and the device can be used repeatedly.

A VED has two parts: a pump, which generates a negative vacuum pressure, and a cylinder, which is closed at one end (Fig. 103-3). The patient applies lubricant to and inserts his penis into the open end of the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. The lubricant helps maintain a tight seal between the VED and the patient's abdomen. Then, the patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient places constriction bands or tension rings at the base of the erect penis. The bands or rings trap arteriolar blood in the corpora cavernosa and reduce venous outflow from the penis. With the assistance of loading cones to protect the glans, these bands or rings can be rolled over the glans penis onto the erect penile shaft. Alternatively, the bands or rings can be first threaded onto the plastic cylinder before the penis is inserted. Once the penis is erect, the band or ring can be rolled off the cylinder onto the base of the penis. However, some patients prefer to apply the band or ring before the penis is erect.[6,31]

FIGURE 103-3

Technique for using a vacuum erection device. (*Reprinted, with permission, from Osbon Erec Aid Esteem Vacuum Therapy System User Guide. Eden Prairie, MN: TIMM Medical Technologies.*)



Assemble your system according to the two-step procedure.

Step 1

Apply Osbon Personal Lubricant™ to the following:

1. two inches inside the open end of the cylinder;
2. the rim of the cylinder that meets the body to form the vacuum seal; and
3. the entire head of the penis.

Applying lubricant properly will help you achieve the best erection possible.

Tip: Trimming the pubic hair around the base of the penis with a pair of scissors may also prove helpful in creating an airtight seal.

Step 2

It is recommended that you stand for this step (the system can also be used when you are sitting or lying down).

Place the lubricated penis inside the cylinder with the label on the cylinder facing up. With one hand, hold the cylinder at a downward 45° angle with the open end snugly against the body.

Tip: Rotate cylinder slightly back and forth to make an airtight seal against the body, make sure the testicles are not drawn into the cylinder.

⑦ The onset of action of the VED is 3 to 20 minutes; a faster onset of 2 to 3 minutes is associated with continued, more experienced use.[31] VEDs are not discreet. That is, a patient's use of a VED is evident to the partner. For this reason, VEDs appear to work best in older patients who are married or who have stable sexual relationships. In this group, VEDs could be considered first-line therapy, and the overall satisfaction rate can be as high as 60% to 80% (range, 27%-94%) in all patients, including those with diabetes mellitus and spinal cord injury.[30,31] VEDs may be used as second-line therapy in patients who do not respond to oral phosphodiesterase type 5 inhibitors,[22] which includes patients who have had a radical prostatectomy or those who do not respond to injectable drug treatments for erectile dysfunction. The combination of a VED with intracavernosal or intraurethral alprostadil[24,32] or a phosphodiesterase type 5 inhibitor is associated with a higher efficacy rate than the use of the VED alone.[16,32,33] As a result, combination therapy sometimes is attempted before penile prosthesis surgery is considered in the patient who fails to respond to a VED alone.

Patients may discontinue using VEDs because they are inconvenient and not discreet. It has been reported that the dropout rate is as high as 56% during the first year of use.[31] Also, 6% to 11% of partners complain that the penis is cool to the touch or is discolored (bluish) in appearance, particularly when constriction bands are used.[22]

Vacuum erection devices are available with battery-operated pumps, which offer convenience, particularly in patients with arthritis of the hands. When choosing a device, patients should select one with a pop-off safety valve that minimizes the likelihood of excessively high vacuum pressure, which can cause penile discomfort, petechiae, or hematoma.[24,31]

Penile pain, bruising, or injury from VEDs most often is caused by the constriction bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the constriction bands are applied for longer than 30 minutes, the penile shaft may turn blue and hurt.[22] Patients may complain that a hinge-like erection is produced in that the penis pivots on the rubber ring or tension band. Patients sometimes fail to ejaculate.[24]

Vacuum erection devices are contraindicated in patients with sickle cell disease or patients with a history of prolonged erections. These patients are prone to priapism, which can be exacerbated by the use of constriction bands with VEDs. The devices also should be used cautiously by patients taking warfarin, as this agent increases the likelihood of penile bruising during use of the device. Finally, VEDs are contraindicated in patients with severe penile curvature.

Pharmacologic Therapy

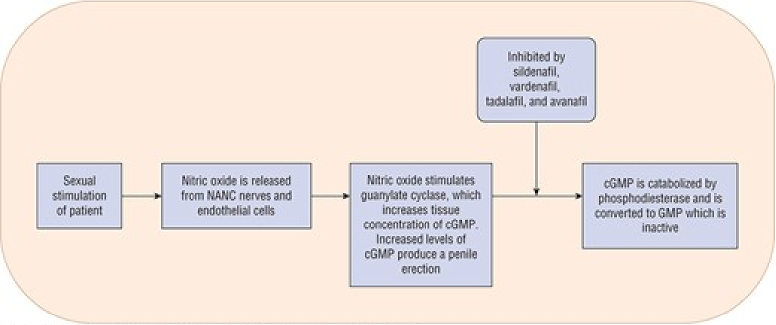
Phosphodiesterase Type 5 Inhibitors

Mechanism

In the presence of sexual stimulation, nitric oxide is released by neurons and endothelial cells in cavernosal tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for the conversion of guanylate triphosphate to cGMP (Fig. 103-4).[22] cGMP is a vasodilatory secondary messenger that activates protein kinase G, which decreases intracellular calcium levels, relaxes smooth muscle, enhances arterial flow to the corpora cavernosa, and increases blood filling of cavernosal sinuses. Catabolism of cGMP in cavernosal tissue is mediated by phosphodiesterase isoenzyme type 5.

FIGURE 103-4

Mechanism of action of phosphodiesterase type 5 inhibitors. All inhibit catabolism of cGMP, a vasodilatory secondary messenger. (cGMP, cyclic guanosine monophosphate; NANC, nonadrenergic noncholinergic.)



Inhibited by sildenafil, vardenafil, tadalafil, and avanafil
Sexual stimulation of patient
Nitric oxide is released from NANC nerves and endothelial cells
Nitric oxide stimulates guanylate cyclase, which increases tissue concentration of cGMP. Increased levels of cGMP produce a penile erection
cGMP is catabolized by phosphodiesterase and is converted to GMP which is inactive

Four competitive, reversible inhibitors of the phosphodiesterase isoenzyme type 5 are marketed for erectile dysfunction in the United States (Table 103-5). Chemically, they are nonhydrolyzable analogs of cGMP and they act by decreasing catabolism and maintaining high concentrations of cGMP in the corpora cavernosa. In effect, this sustains a penile erection. However, these medications are not specific for phosphodiesterase isoenzyme type 5. They also inhibit other phosphodiesterase isoenzymes in other tissues and organs, which produces some of the unwanted side effects of this medication class.[34]

TABLE 103-5

Pharmacodynamics and Pharmacokinetics of Phosphodiesterase Inhibitors

	Sildenafil (Viagra)	**Vardenafil** (Levitra/Staxyn)	**Tadalafil** (Cialis)	Avanafil[36,37] (Stendra)
Inhibits PDE-5	Yes	Yes	Yes	Yes

Selectivity of Other Phosphodiesterase Isoenzymes

More than 11 different phosphodiesterase isoenzymes have been identified; however, the physiologic effects of stimulation and inhibition of some of these isoenzymes remain to be elucidated.[13,34] The four commercially available phosphodiesterase type 5 inhibitors exhibit variable selectivity for phosphodiesterase 5 as opposed to phosphodiesterase types 1, 6, and 11. These differences are displayed in Table 103-5.

Phosphodiesterase isoenzyme 1 is found in the peripheral vasculature. Inhibition of this isoenzyme has been linked with peripheral vasodilation, which can lower blood pressure, and cause flushing and reflex tachycardia, particularly in patients taking nitrates, alpha-adrenergic antagonists, or some antihypertensives.[37] Among the phosphodiesterase type 5 inhibitors, tadalafil and avanafil have much less selectivity for phosphodiesterase type 1 as compared with phosphodiesterase type 5. As a result, tadalafil and avanafil are less likely to cause hypotension as compared with sildenafil and vardenafil.[36,37]

Phosphodiesterase isoenzyme type 6 is localized to the rods and cones of the retina. Inhibition of this isoenzyme has been associated with blurred vision and cyanopsia. Sildenafil is the most potent inhibitor of phosphodiesterase isoenzyme type 6, vardenafil is an intermediate inhibitor, and tadalafil and avanafil are the least potent inhibitors.[35,37]

Phosphodiesterase isoenzyme type 11 is localized to skeletal muscle. Inhibition of this isoenzyme has been associated with myalgia and back muscle pain. Tadalafil exerts the greatest inhibitory activity against phosphodiesterase type 11.[35,37]

Efficacy

Because of their apparent effectiveness, convenient oral route of administration, and comparatively low incidence of serious adverse effects, phosphodiesterase type 5 inhibitors are first-line therapy for erectile dysfunction. They allow for discreet use. Although not based on direct comparison trials, all four commercially available phosphodiesterase type 5 inhibitors are considered to be equally effective and comparable in safety and tolerability.[13,34] Patient preference studies show that some patients may choose a particular agent because of the preferences of the sexual partner or the onset, duration, or cost of a specific medication.[38] For example, for a patient with infrequent sexual intercourse, sildenafil or vardenafil is a good choice; for a patient with frequent sexual intercourse, tadalafil may be preferred; and for a patient with unscheduled periodic intercourse, a fast-acting agent like vardenafil ODT may be preferred.[39]

Usual starting and maintenance dose regimens are included in Table 103-4.

In the presence of sexual stimulation and in doses of 25 to 100 mg, sildenafil produces satisfactory erections in 56% to 82% of patients, independent of the etiology of erectile dysfunction. Similar results are documented in the product labeling for the other agents in this class (65%-80% for vardenafil, 62%-77% for tadalafil, and 57%-77% for avanafil). The change in IIEF-EF score for a phosphodiesterase inhibitor is approximately 5.6 to 7.4 points.[25] Response rates are in the lower range for patients with diabetes mellitus or after radical prostatectomy, or those with severe vascular disease, probably due to neuropathy, or surgery-related nerve damage.[22] The effectiveness of the drugs appears to be dose-related.

⑧ Approximately 30% to 40% of patients do not respond to phosphodiesterase type 5 inhibitors.[22] At least half of nonresponders benefit from education on proper use of the drugs.[32] Therefore, follow-up is always recommended after a phosphodiesterase type 5 inhibitor is initiated to see if additional education is needed for the following points: (a) patients must engage in sexual stimulation (foreplay) for the best response;[16,22] (b) sildenafil and vardenafil should be taken on an empty stomach, at least 2 hours before meals, for the fastest response, but tadalafil and avanafil can be taken without regard to meals; (c) patients who do not respond to the first dose should continue with the phosphodiesterase type 5 inhibitor for at least seven to eight doses before failure is declared, as increasing success rates are reported with sequential dose administration;[16,32] (d) some patients require dosage titration up to 100-mg sildenafil, 20-mg vardenafil, 20-mg tadalafil, or 200-mg avanafil for a response;[13] (e) patients should avoid excessive alcohol intake, which can cause drowsiness and hypotension and worsen erectile dysfunction; (f) treatment of concomitant medical illnesses that contribute to erectile dysfunction (eg, diabetes mellitus, hypertension, and hypogonadism) should be optimized (if the patient has depression because of divorce or loss of a sexual partner, or has performance anxiety, psychologic counseling may be helpful).[22]

The phosphodiesterase type 5 inhibitors should not be used by patients with normal erectile function. Also, according to FDA-approved labeling, the drugs should not be used in combination with other forms of therapy for erectile dysfunction because prolonged erections (which may lead to priapism) may result.[22] Phosphodiesterase type 5 inhibitors should be avoided in patients predisposed to developing priapism, including men with sickle cell anemia, leukemia, or multiple myeloma.

Long-term use of phosphodiesterase type 5 inhibitors for up to 10 consecutive years continues to be effective and is not associated with tachyphylaxis.[6] The voluntary discontinuation rate among patients has been reported as high as 50% after 6 to 24 months of treatment, despite a positive treatment response.[13] This phenomenon is likely due to the high out-of-pocket costs of phosphodiesterase type 5 inhibitors, the inconvenient process of obtaining the medication, adverse drug effects, the patient's loss of interest in sexual intercourse, partner-related problems (marital problems/no partner) or the efficacy of the medication being below the patient's expectations because of worsening of the patient's underlying erectile dysfunction disease.[6,40,41]

Despite the initial effectiveness of phosphodiesterase type 5 inhibitors and the measures to salvage patients with reeducation, some patients with severe vascular or neurologic disease will show minimal or no response to maximum doses of a phosphodiesterase type 5 inhibitor. Various strategies have been attempted in this subgroup of patients, including the following:

1. The effectiveness of switching from one phosphodiesterase type 5 inhibitor to another when the patient does not respond to an initial agent is controversial, although it is clear that some patients prefer one agent over another.[24] Controlled clinical trials in larger patient groups are needed before this strategy is used as routine treatment.
2. Switching the patient from an as needed to a daily regimen of tadalafil may be reasonable when the patient has difficulty coordinating the timing of tadalafil before meals or sexual intercourse.[6,42] However, a daily dose regimen is more expensive than an on-demand regimen.
3. Adding an as-needed shorter-acting phosphodiesterase inhibitor to a low daily dose of tadalafil regimen.[16]
4. High-dose phosphodiesterase type 5 inhibitor treatment (eg, sildenafil 200 mg) has been used anecdotally. However, such doses are also associated with a higher frequency of adverse effects.[43]
5. In older patients (age greater than or equal to 65 years) with late-onset hypogonadism and erectile dysfunction, correcting the former with testosterone supplementation improves the response to a phosphodiesterase type 5 inhibitor.[22,32]
6. Phosphodiesterase type 5 inhibitors have been combined with intracavernosal or intraurethral alprostadil in selected patients. This allows combining agents with 2 different vasodilatory MOA.[22,44]

Pharmacokinetic parameters of the phosphodiesterase inhibitors are listed in Table 103-5.[35]

Sildenafil and the conventional oral formulation of vardenafil have similar pharmacokinetic profiles. Both drugs have a 1-hour onset of action and short duration of action. Oral absorption is significantly delayed by 1 hour when either drug is taken within 2 hours of a fatty meal.[35] An oral disintegrating tablet (ODT) formulation of vardenafil, which dissolves on the tongue, has 1.2- to 1.4-fold higher bioavailability than the conventional oral tablet when taken without water. Unlike the conventional tablet, the ODT formulation should be taken without water, which allows discretion, and is not susceptible to a drug–food interaction. In addition, the ODT dissolves on the tongue and does not require swallowing. Thus, patients with dysphagia, who comprise almost 25% of patients who are 50 years of age or older, could easily use this formulation.[34,39] When compared with the other phosphodiesterase type 5 inhibitors, tadalafil has a slower onset of action of 2 hours and a prolonged duration of action up to 36 hours. Food does not affect the rate of absorption of tadalafil. Tadalafil offers greater spontaneity for patients, as one dose can last through an entire weekend and it allows for multiple acts of sexual intercourse over multiple days with a single dose. Avanafil has an onset of action of 15 minutes; its onset is faster than, but is similar in duration to sildenafil and vardenafil. A high-fat meal will delay the absorption and reduce total amount absorbed by avanafil.[16,24,37]

The onset of action of these agents has undergone reexamination to assess how soon after drug administration patients can expect to have an erection suitable for intercourse. Although up to 50% of patients may develop an erection within 20 to 30 minutes of sildenafil 100 mg, vardenafil 20 mg, tadalafil 20 mg, or avanafil 200 mg, the rest of the patients may require a full hour to achieve an adequate erectile response.[35] Therefore, patients should be instructed to allow adequate time for the drug to work. In addition, sildenafil and vardenafil have been reported to be effective in some patients up to 12 hours after dosing, and tadalafil is effective up to 36 hours after dosing, which is long after plasma concentrations have declined. It has been hypothesized that this may be due to the continued intracellular action of the phosphodiesterase type 5 inhibitor. Further study is needed to determine if avanafil's duration of action is longer than 6 hours.

Concomitant ingestion of ethanol with phosphodiesterase type 5 inhibitors can result in orthostatic hypotension and drowsiness. Therefore, the manufacturer recommends that patients avoid ethanol when taking these medications.

All four phosphodiesterase type 5 inhibitors are hepatically catabolized principally by the cytochrome P450 3A4 microsomal isoenzyme. Other P450 isoenzymes and/or other hepatic enzymes are minor routes of catabolism (see Table 103-5). Sildenafil has an active metabolite, which is excreted primarily in the urine. Tadalafil has a clinically insignificant active metabolite. However, 36% of tadalafil drug is renally eliminated. Thus, both sildenafil and tadalafil doses should be reduced in patients with significant renal impairment. Vardenafil and avanafil have active metabolites that are largely excreted in feces. No specific dosage reduction of these medications is recommended in patients with reduced renal function because of the intermittent nature of the dosing schedule. However, avanafil is not recommended when the creatinine clearance is less than 30 mL/min (0.5 mL/s) (see Table 103-5).

Dosing

The usual oral doses of the phosphodiesterase type 5 inhibitors are listed in Table 103-4. Sildenafil, vardenafil (oral swallow tablets), and avanafil should be taken on demand at least 30 to 60 minutes before sexual intercourse. Vardenafil ODT and tadalafil should be taken 15 minutes and 2 hours, respectively, before sexual intercourse. The agents vary as to whether doses must be adjusted for patients aged 65 years and older and those with compromised hepatic or renal function. Patients should be advised to take no more than the amount prescribed and not more than one dose per day.[45] Doses higher than those recommended have been described in the published literature (eg., sildenafil 200 mg).[43] However, such dosing regimens have not consistently produced improved erectile responses.

For patients who do not respond to an adequate course of on-demand phosphodiesterase type 5 inhibitors for erectile dysfunction, daily low dosing of tadalafil may improve endothelial function in cavernosal tissue. That is, regular use of phosphodiesterase type 5 inhibitors may activate endothelial nitric oxide synthase, increase local concentrations of cGMP, which may increase oxygen tension, improve blood flow, and reduce endothelial damage and fibrosis in the corpora cavernosa.[46] Other potential advantages of this daily low dosing regimen include a lower potential for dose-related adverse effects and increased spontaneity of sexual intercourse. However, disadvantages of the daily low-dose regimen are the high cost of treatment; patients with more severe erectile dysfunction, who may require higher doses of a phosphodiesterase type 5 inhibitor, may not respond.[22,28,47] Although clinical trials of daily dosing of tadalafil 10 and 20 mg,[48,49] have been published, the only FDA-approved labeling is for daily dosing of tadalafil 2.5 or 5 mg.

Adverse Effects

Most adverse effects of the phosphodiesterase type 5 inhibitors are mild or moderate and are self-limited; and tolerance to the adverse effects develops with continued use.[28,47,50,51] The rates of drug discontinuation because of adverse effects are low, ranging from 2.1% to 25%, and are similar for all four agents. In usual doses, the most common adverse effects are headache (11%), facial flushing (12%), dyspepsia (5%), nasal congestion (3.4%), and dizziness (3%), all of which are dose-related and result from vasodilation or smooth muscle relaxation secondary to inhibition of phosphodiesterase isoenzyme type 1 or 5 in cardiac or vascular tissues.[47,50] However, some differences in the adverse reaction profile do exist. Sildenafil and vardenafil use is associated with more vascular and ocular adverse effects due to its inhibition of phosphodiesterase type 1 and 6, and tadalafil is associated with more lower back and limb pain and myalgia due to its greater inhibition of phosphodiesterase type 11.[35,50–52] Avanafil may be the best-tolerated agent because of its highly selective inhibition of phosphodiesterase type 5 and short half-life.[36–38,53]

Sildenafil and vardenafil produce an 8 to 10 mm Hg decrease in systolic and a 5 to 8 mm Hg decrease in diastolic blood pressure starting approximately 1 hour after a dose is taken and lasting for 4 hours. Most patients are asymptomatic as a result of these blood pressure changes, but some patients, particularly those taking multiple antihypertensives or nitrates or those with baseline hypotension, may develop dizziness or palpitations. Avanafil and tadalafil produce decreases in systolic and diastolic blood pressure that are smaller than those associated with sildenafil and vardenafil, although the decrements may be greater when they are used along with other antihypertensives or α-adrenergic antagonists.[47] All phosphodiesterase type 5 inhibitors must be used with caution in patients with cardiovascular disease because of the cardiac risk inherent to vigorous sexual activity. The management approach for such patients, as described in the recommendations of the Princeton Consensus Guideline Conference III,[26] should be applied to all the patients in whom phosphodiesterase type 5 inhibitors are being considered for use (see Table 103-3). If a patient who has cardiovascular disease develops angina during sexual intercourse after having taken a phosphodiesterase type 5 inhibitor, the patient should immediately stop and rest for the next 5 to 10 minutes. If angina does not resolve after 20-30 minutes, or if the patient develops additional anginal symptoms, the patient should be taken to the nearest emergency room.[54]

Sildenafil, vardenafil, and avanafil cause increased sensitivity to light, blurred vision, or transient loss of blue–green color discrimination in 2% to 3% of patients. This adverse effect is dose-related with the incidence increasing to 40% to 50% in patients taking sildenafil 200 mg.[47,55] These effects result from inhibition of phosphodiesterase type 6 in the photoreceptor cells of retinal rods and cones. Visual adverse effects commonly occur 1 to 2 hours after oral dosing when peak serum concentrations are achieved.[55] Avanafil has moderate and tadalafil has minimal to no inhibitory activity against phosphodiesterase type 6, and they are associated with a lower incidence of visual adverse effects (less than 1%) when compared to sildenafil and vardenafil.[47] Nevertheless, according to current product labeling, all phosphodiesterase type 5 inhibitors should be stopped immediately if the patient reports vision loss and should be used cautiously in patients at risk for retinitis pigmentosa, a genetic disease associated with retinal phosphodiesterase deficiency.

Nonarteritic anterior ischemic optic neuropathy (NAION) is a sudden, unilateral, painless blindness, which may be irreversible. Isolated cases of NAION have been associated with phosphodiesterase type 5 inhibitor use.[50] NAION has developed at variable and unpredictable times after starting a phosphodiesterase type 5 inhibitor, ranging from 6 hours to months or years after the first dose. Although a cause–effect relationship has not been established, it has been proposed that the blood pressure-lowering effects of these medications may decrease blood flow to the optic nerve and lead to a sudden unilateral decrease in vision.[56] Because NAION may lead to permanent vision loss, the FDA has required inclusion of warnings on the product labeling of phosphodiesterase type 5 inhibitors. Specifically, before receiving these agents, patients at risk for NAION should be evaluated by an ophthalmologist, risk factors for NAION should be addressed, and the patient should be cautioned against using a phosphodiesterase type 5 inhibitor.[47,50,56]

Patients at risk of NAION include a wide variety of patients: those with glaucoma, macular degeneration, diabetic retinopathy, dyslipidemia, or hypertension, those who have undergone eye surgery or have experienced eye trauma, patients who are aged 50 years or more, or smokers. A patient who experiences sudden vision loss in one eye while taking a phosphodiesterase type 5 inhibitor should be evaluated for NAION before continuing treatment. If NAION is present, the phosphodiesterase type 5 inhibitor should be discontinued as there is a 15% to 25% risk of developing NAION in the other eye in the ensuing 5 to 10 years.[56]

Acute unilateral hearing loss has also been reported after use of a phosphodiesterase type 5 inhibitor. A cause–effect relationship has not been established. In the cases reported, the hearing loss occurred within 1 to 3 days of starting treatment; it was variably accompanied by tinnitus or vertigo, and often resulted in residual hearing loss despite discontinuation of the phosphodiesterase type 5 inhibitor.[47] The product labeling now includes a warning that a phosphodiesterase type 5 inhibitor should be immediately stopped, and the patient should see a physician if sudden hearing loss develops.[50]

Priapism is a rare adverse effect of phosphodiesterase type 5 inhibitors, particularly sildenafil and vardenafil. Priapism has been associated with excessive doses of the phosphodiesterase type 5 inhibitor or when they are used along with other erectogenic drugs.[24]

Sildenafil use has been associated with an increased risk of melanoma. The proposed mechanism is that phosphodiesterase type 5 inhibition activates *BRAF*, a human gene that produces a protein that causes proliferation of melanoma cells. However, a cause–effect relationship has not been established.[57,58]

Recommendations for adverse effect monitoring are included in Table 103-6.

TABLE 103-6

Drug Monitoring Table

Drug	**Adverse Drug Reaction**	**Monitoring Parameter**	**Comments**
Phosphodiesterase Inhibitor			
Sildenafil	- Headache	- Clinical	- Discontinue sildenafil if the patient has any visual or hearing loss and

	- Flushing - Dyspepsia - Nasal congestion - Cyanopsia - NAION - Hypotension - Priapism - Hearing loss	symptoms of erectile dysfunction - Visual complaints, loss of vision - Hearing loss - Blood pressure - Pulse	refer the patient to a physician - If the patient is taking any antihypertensives, stabilize blood pressure before starting sildenafil - If the patient develops priapism, he should proceed to the emergency department - If the patient has a bleeding disorder, use cautiously
Vardenafil	- Headache - Flushing - Dyspepsia - Nasal congestion - Cyanopsia - NAION - Hypotension - QT interval prolongation on EKG - Priapism - Hearing loss	- Clinical symptoms of erectile dysfunction - Visual complaints, loss of vision - Hearing loss - Blood pressure - Pulse - Palpitations or dizziness	- Discontinue vardenafil if the patient has any visual or hearing loss and refer the patient to a physician - If the patient is taking any antihypertensives, stabilize blood pressure before starting vardenafil - If the patient has palpitations or dizziness, check EKG. If QT prolongation is present, refer the patient for appropriate medical care. - If the patient develops priapism, he should proceed to the emergency department - If the patient has a bleeding disorder, use cautiously
Tadalafil	- Headache - Flushing - Dyspepsia - Nasal congestion - Cyanopsia - Hearing loss - NAION - Hypotension - Lower backor lower extremity pain or myalgia - Priapism	- Clinical symptoms of erectile dysfunction - Visual complaints, loss of vision - Hearing loss - Blood pressure - Pulse - Palpitations or dizziness - Myalgia	- Discontinue tadalafil if the patient has any visual or hearing loss and refer the patient to a physician - If the patient is taking any antihypertensives, stabilize blood pressure before starting tadalafil - If the patient develops priapism, he should proceed to the emergency department - If the patient has a bleeding disorder, use cautiously - Muscle pain is dose-related
Avanafil	- Headache - Flushing - Dyspepsia - Nasal congestion - Cyanopsia - Hearing loss - NAION - Hypotension	- Clinical symptoms of erectile dysfunction - Visual complaints, loss of vision - Blood	- Discontinue avanafil if the patient has any visual or hearing loss and refer the patient to a physician - If the patient is taking any antihypertensives, stabilize blood pressure before starting avanafil - If the patient develops priapism, he should proceed to the emergency department - If the patient has a bleeding disorder, use cautiously

	• Priapism	pressure • Pulse • Palpitations or dizziness • Hearing loss	
Prostaglandin E_1			
Alprostadil, intracavernosal	• Penile pain • Hematoma at injection site • Priapism • Hypotension • Fibrotic nodules along penile shaft • Decreased blood pressure • Dizziness	• Clinical symptoms of erectile dysfunction • Presence of hematoma or fibrotic nodules • Blood pressure • Pulse	• Penile pain responds to acetaminophen • To avoid hematoma, apply pressure to injection site for 5-10 minutes after injection • If the patient develops priapism, he should proceed to the emergency department • Fibrotic nodules are rare but may occur after repeated injections. These may cause curvature of the penis during an erection and this requires assessment by a urologist • Hypotension and dizziness are uncommon and are associated with inadvertent venous injection of the drug
Alprostadil, intraurethral	• Aching pain in penis, testicles, legs, and perineum • Urethral burning, bleeding, or tearing • Priapism • Hypotension • Dizziness • Female partner may experience vaginal pain and burning sensation	• Clinical symptoms of erectile dysfunction • Urethral injury as evidenced by pain, bleeding, or tissue damage • Blood pressure • Pulse	• Burning pain usually resolves spontaneously. If urethral injury is suspected, this requires assessment by a urologist. Pain experienced by the female partner is due to leakage of medication from male urethra into vagina. Pain will usually resolve spontaneously • If the patient develops priapism, he should proceed to the emergency department • Hypotension and dizziness are uncommon, occurring in only 2%-3% of patients, and are associated with systemic absorption of the drugs • Alprostadil is embryotoxic and contact must be avoided if the female sex partner is pregnant. Males should use condoms if female is pregnant
Testosterone Supplements			
Methyltestosterone	• Sodium and water retention • Hyperlipidemia • Polycythemia • Gynecomastia • Sleep apnea, worsening • Increased libido • Mood swings • Oligospermia • Hepatotoxicity • Venous	• Clinical symptoms of erectile dysfunction • Physical exam for edema • Blood pressure • Serum lipids, hematocrit, hepatic transaminases,	• Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55% (0.55), methyltestosterone should be discontinued. Testosterone supplements may worsen lower urinary tract symptoms (LUTS) in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. May increase the risk of nonfatal myocardial infarction or death. Use precautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected

	thromboembolism • Prostate enlargement	prostate-specific antigen, serum testosterone	
Testosterone cypionate or enanthate Testosterone undecanoate	• Sodium and water retention • Hyperlipidemia • Polycythemia • Gynecomastia • Sleep apnea, worsening • Increased libido • Oligospermia • Mood swings • Hepatotoxicity • Venous thromboembolism • Prostate enlargement • Injection site pain, pruritis • Pulmonary oil microembolism (POME), testosterone undecanoate only • Anaphylactic reactions • Prostate enlargement • Sodium and water retention • Hyperlipidemia • Polycythemia • Gynecomastia • Sleep apnea, worsening • Increased libido • Oligospermia • Mood swings • Hepatotoxicity	• Clinical symptoms of erectile dysfunction • Physical exam for edema • Blood pressure • Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen • Clinical symptoms of erectile dysfunction • Physical exam for edema, cough, shortness of breath • Blood pressure • Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen	• Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55% (0.55), testosterone supplement should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. These formulations produce supraphysiologic serum concentrations of testosterone. Mood swings have been reported with these agents. May increase the risk of nonfatal myocardial infarction or death. Use cautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected • Discontinue if the patient has signs of hepatoxicity. If hematocrit exceeds 55% (0.55), testosterone supplement should be discontinued. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. These formulations produce supraphysiologic serum concentrations of testosterone. Mood swings have been reported with these agents. May increase the risk of nonfatal myocardial infarction or death. Use cautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected • Signs of POME include cough, dyspnea, chest pain, and syncope, usually within 30 minutes of testosterone undecanoate injection. This medication should only be administered by a healthcare provider or in setting which is certified through a Risk Evaluation and Mitigation Strategy program
Testosterone patch	• Sodium and water retention • Hyperlipidemia • Gynecomastia • Sleep apnea,	• Clinical symptoms of erectile dysfunction • Physical exam	• Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. Contact dermatitis has been associated with the alcohol-based agent used to enhance transdermal drug absorption. It responds to topical corticosteroids. Of significance, hepatotoxicity has not been

	worsening • Increased libido • Contact dermatitis • Application site erythema, pruritus • Prostate enlargement	for edema • Blood pressure • Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen, serum testosterone	reported with transdermal patches. May increase the risk of nonfatal myocardial infarction or death. Use precautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected. Adverse effects of mood swings and polycythemia are less likely with patch than with injectable formulations
Testosterone transdermal gel/spray/axillary solution	• Sodium and water retention • Hyperlipidemia • Polycythemia • Gynecomastia • Sleep apnea, worsening • Increased libido • Dermatitis • Application site erythema • pruritis, • Prostate enlargement	• Clinical symptoms of erectile dysfunction • Physical exam for edema • Blood pressure • Serum lipids, hematocrit, hepatic transaminases, prostate-specific antigen, serum testosterone	• Do not interchange topical formulations. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer Use is contraindicated in pregnant women or women who are likely to become pregnant, or women who breast feed infants. Women and children who have inadvertent skin exposure to these formulations may become virilized. If hematocrit exceeds 55% (0.55), testosterone supplement should be discontinued. May increase the risk of nonfatal myocardial infarction or death. Use precautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected. With transdermal sprays, REMS assessments must be submitted to the FDA
Testosterone gel, intranasal	• Rhinorrhea, nose bleeds, nose pain • Sore throat • Sodium and water retention • Hyperlipidemia • Polycythemia • Gynecomastia • Sleep apnea, worsening • Increased libido • Dermatitis • Application site erythema • pruritis, • Prostate enlargement	• Clinical symptoms of erectile dysfunction • Physical exam for edema • Blood pressure • Serum lipids, hematocrit, hepatic transaminases, prostate specific antigen, serum testosterone	• Discontinue if severe rhinitis occurs. • Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. Use is contraindicated in pregnant women or women who are likely to become pregnant, or women who breast feed infants. Women and children who have inadvertent skin exposure to these formulations may become virilized. If hematocrit exceeds 55% (0.55), testosterone supplement should be discontinued. May increase the risk of nonfatal myocardial infarction or death. Use precautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected. With transdermal sprays, REMS (risk evaluation and mitigation strategies) assessments must be submitted to the US Food and Drug Administration
Testosterone	• Sodium and water	• Clinical	• Subcutaneous pellet implant may be extruded with loss of the dose.

subcutaneous implant	retention • Hyperlipidemia • Polycythemia • Gynecomastia • Sleep apnea, worsening • Increased libido • Mood swings • Oligospermia • Hepatotoxicity • Prostate enlargement • Pain and infection at the implant site	symptoms of erectile dysfunction • Physical exam for edema • Blood pressure • Serum lipids, hematocrit, hepatic transaminases, prostate specific antigen, serum testosterone	Androgen-related adverse effects may persist for a long time after drug administration unless the implant is removed. If hematocrit exceeds 55% (0.55), testosterone implant should be removed. Testosterone supplements may worsen LUTS in patients with BPH. It is contraindicated in patients with untreated prostate cancer or men with breast cancer. May increase the risk of nonfatal myocardial infarction or death. Use cautiously in patients with a significant cardiovascular history. Discontinue if venous thromboembolism is suspected

LUTS, lower urinary tract symptoms.

Drug Interactions

Approximately 8% of patients taking organic nitrates may develop sudden, severe hypotension if they also take a phosphodiesterase type 5 inhibitor. Decreased blood pressure results from two major factors: (a) organic nitrates on their own produce hypotension and (b) organic nitrates are nitric oxide donors, which can stimulate the activity of guanylate cyclase and increase tissue levels of cGMP.[35,54] For this reason, phosphodiesterase type 5 inhibitor use is contraindicated in patients taking nitrates given by any route at scheduled times or intermittently. Furthermore, nitrates should be withheld for 24 hours after sildenafil, vardenafil, or avanafil administration and for 48 hours after tadalafil administration.[26,35] Furthermore, if a patient who has taken a phosphodiesterase type 5 inhibitor requires medical treatment of angina, non-nitrate-containing agents (eg, calcium channel blocker, β-adrenergic antagonist, and morphine) should be used.

If severe hypotension occurs after exposure to nitrates and a phosphodiesterase type 5 inhibitor, the patient should be placed in a Trendelenburg position and aggressive fluid administration initiated. If severe hypotension continues, parenteral β-adrenergic agonists (eg, dopamine) should be administered cautiously.[26]

Once a phosphodiesterase type 5 inhibitor has been discontinued, a nitrate may be taken 24 hours after the last dose of sildenafil, vardenafil, or avanafil, or 48 hours after the last dose of tadalafil.[54]

Interestingly, dietary sources of nitrates, nitrites, or L-arginine (a precursor for nitrates) do not interact with phosphodiesterase type 5 inhibitors. This is because dietary sources do not increase circulating or tissue levels of nitric oxide in humans.

The phosphodiesterase type 5 inhibitors have a low potential to interact with most antihypertensive medications.[16,17,19] However, small decreases in blood pressure with clinically symptomatic orthostatic hypotension have been described in some patients taking phosphodiesterase type 5 inhibitors and α-adrenergic antagonists. The degree of hypotension that develops is dependent on several factors: (a) stability of patient's blood pressure prior to taking both drugs; (b) dose of the α-adrenergic antagonist used; (c) particular α-adrenergic antagonist used; (d) particular phosphodiesterase type 5 inhibitor used; and (e) timing of administration of both drugs. The drug interaction produces less hypotension when the patient has stable blood pressure prior to taking both drugs; a low dose of alpha-adrenergic antagonist is taken; a uroselective (eg, tamsulosin or silodosin) or extended-release formulation of an alpha-adrenergic antagonist (eg, alfuzosin, or modified-release doxazosin) is used; tadalafil is preferentially prescribed over sildenafil, vardenafil, or avanafil; and an interval of 4 to 6 hours separates the doses of the alpha-adrenergic antagonist and phosphodiesterase type 5 inhibitor.[24,39]

Hepatic metabolism of all four phosphodiesterase type 5 inhibitors can be inhibited by strong enzyme inhibitors of CYP 3A4, including fluvoxamine, fluoxetine, nefazodone, verapamil, diltiazem, cimetidine, erythromycin, clarithromycin, itraconazole, ketoconazole, fluconazole itraconazole, atazanavir, indinavir, ritonavir, saquinavir, and grapefruit juice. Potent CYP 3A4 inhibitors may increase plasma levels of phosphodiesterase type 5 inhibitors by threefold or more. Lower starting doses of phosphodiesterase type 5 inhibitor should be used in these patients to minimize dose-related adverse effects, including cyanopsia, hypotension, flushing, nasal congestion, and priapism (see Table 103-4). Similarly, CYP 3A4 inducers, including rifampin, carbamazepine, phenytoin, and phenobarbital, can decrease plasma levels of phosphodiesterase type 5 inhibitors. Higher starting doses of phosphodiesterase type 5 inhibitors should be used in these patients.

If used with type 1A antiarrhythmics (eg, quinidine or procainamide) or type 3 antiarrhythmics (eg, sotalol, amiodarone), vardenafil can prolong the QT interval. This is a unique drug interaction of vardenafil and not a pharmacologic class effect.

Testosterone Replacement Regimens

Mechanism

⑨ Testosterone replacement regimens supply exogenous testosterone and restore serum testosterone levels to the normal range of 300 to 1,100 ng/dL (10.4-38.2 nmol/L). In so doing, testosterone replacement regimens correct symptoms of hypogonadism, which include malaise, loss of muscle strength, depressed mood, and decreased libido.[11]

Testosterone can directly stimulate androgen receptors in the CNS and is thought to be responsible for maintaining normal sexual drive. In addition, testosterone may stimulate nitric oxide synthase, thereby increasing cavernosal concentrations of nitric oxide, and enhancing the effects of phosphodiesterase type 5 in cavernosal tissue.[11] Testosterone may also enhance relaxation and blood filling of the corpora cavernosa by downregulating RhoA-ROCK, an enzymatic pathway responsible for calcium transport into penile smooth muscle cells.[59]

Indications

Although multiple guidelines on testosterone replacement have been published, 4 commonly used ones include the recommendations from the Endocrine Society,[12] British Society for Sexual Medicine,[16] American Urological Association,[60] and the European Association of Urology.[61] A recent comparison of published guidelines is also available.[62]

Testosterone replacement regimens are indicated in symptomatic patients with primary, secondary, or mixed hypogonadism, as confirmed with serum concentrations of testosterone. Although the threshold serum total testosterone level that defines hypogonadism varies with specific published guidelines, usually a serum total testosterone less than 230- to 350 ng/dL (8.0-12.2 nmol/L) is used.[11,12,60]

Serum testosterone concentrations typically are measured in the early morning between 7 am and 11 am because the secretion pattern of this hormone follows a circadian pattern, with highest serum concentrations in the morning hours and the lowest level at night (approximately 10 pm). A low measured serum testosterone level is confirmed with a repeat measurement on a separate day, optimally 4 weeks later. Confirmation of a low serum testosterone level is essential because of an approximate 10% intra-individual variation of measured levels and variable performance characteristics of various testosterone assays.[11,12,60,61] Simultaneous serum luteinizing hormone levels help to distinguish patients with primary hypogonadism, who have elevated luteinizing hormone levels, from those with secondary hypogonadism, who have decreased luteinizing hormone levels.[12] In men with equivocal serum total testosterone levels, it is recommended to obtain free testosterone levels.[63]

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels, patients who have asymptomatic hypogonadism, or patients with isolated erectile dysfunction as the only sign of hypogonadism.

Efficacy

Testosterone replacement regimens restore muscle strength and sexual drive, promote erythropoiesis, and improve mood, cognition, and bone density in adult patients with hypogonadism.[12,59,60] Testosterone replacement regimens do not directly correct erectile dysfunction; instead, they improve libido, thereby correcting secondary erectile dysfunction. Although testosterone replacement regimens may correct the serum testosterone level within days, observable clinical improvements make take weeks after the start of testosterone replacement. For example, increased libido may be evident at 6 weeks, improvements in erectile dysfunction or increase in muscle mass may take months. For this reason, a minimum effective clinical trial is considered 3 to 6 months.[12,60]

No additional benefit has been demonstrated for large doses of testosterone, which can increase the serum testosterone level from the low end to the upper end of the normal range or to the above-normal range.[60]

Testosterone replacement regimens can be administered parenterally, orally, transdermally, or intransally (see Table 103-4).[63] Intramuscular injections of testosterone enanthate and cypionate are the preferred treatment for symptomatic patients with primary or secondary hypogonadism because they are effective, inexpensive, and not associated with the bioavailability problems or hepatotoxic adverse effects of oral androgens.[60] Patients generally require dosing every 2 to 4 weeks. A longer-acting depot intramuscular formulation of testosterone undecanoate, which can be dosed every 10 weeks, offers greater convenience but is more expensive than testosterone enanthate or cypionate. Testosterone undecanoate has been associated with pulmonary oil embolism and anaphylactic reactions that can necessitate hospitalization.[60] For this reason, testosterone undecanoate is restricted to settings certified through a Risk Evaluation and Mitigation Strategies Program. A subcutaneous implant of testosterone pellets lasts 3 to 6 months, but it requires a surgical incision in the forearm. Extrusion has been reported in up to 8.5% of treated patients and results in loss of drug effect.

Oral formulations are associated with hepatotoxicity and are not recommended.[60] Although convenient for the patient, testosterone patches, gels, and sprays are much more expensive than testosterone enanthate or cypionate.[60] An intranasal testosterone gel formulation avoids inadvertent transfer of testosterone to others, as can occur with some other transdermal gel formulations. However, the intranasal formulation must be taken 3 times a day, which is inconvenient.[63] Therefore, the transdermal and nasal formulations should be reserved for patients who refuse injectable testosterone.

The ideal testosterone replacement regimen would mimic the normal circadian pattern of serum testosterone concentrations such that peak and trough concentrations occur in the early morning and late afternoon, respectively; produce serum concentrations in the normal range; produce serum concentrations of dihydrotestosterone and estradiol, which are metabolites of testosterone, that mimic the normal physiologic pattern; and produce minimal adverse effects. The ideal replacement regimen should be inexpensive and be convenient for the patient to use. Table 103-4 compares commercially available testosterone replacement regimens for these characteristics and shows that an ideal regimen has yet to be identified.[59–62]

The dropout rate with testosterone supplementation is high. Approximately 30% and 85% of patients stop testosterone replacement after 6 and 12 months, respectively. The reasons for this include the cost of the medication, slow onset of response, and inadequate perceived benefit.[12]

Pharmacokinetics

Natural testosterone has poor oral bioavailability because of extensive first-pass hepatic metabolism; therefore, large doses must be taken. To improve oral bioavailability, alkylated derivatives were formulated. Of these derivatives, methyltestosterone and fluoxymesterone are more resistant to hepatic catabolism and can be taken in smaller daily doses, which are theoretically safer. However, oral alkylated derivatives of testosterone are not metabolized to dihydrotestosterone or estradiol, are associated with a higher incidence of serious hepatotoxicity, and therefore are not preferred for management of hypogonadism.

Several testosterone esters have been formulated for intramuscular injection, with different durations of action (see Table 103-4). The shorter-acting testosterone propionate, which required dosing three times per week, has been discontinued and replaced with testosterone cypionate or enanthate, which can be dosed every 2, 4, or 6 weeks in most patients. These testosterone formulations produce supraphysiologic serum testosterone levels 2 to 4 days after each dose, which have been linked to mood swings and polycythemia in some patients.[60]

After the first and second doses, which are given 4 weeks apart, intramuscular injections of testosterone undecanoate generally last 10 weeks. An even longer-acting parenteral testosterone is available as a subcutaneous implant for dosing every 3 to 6 months.[60]

Transdermal testosterone replacement regimens can be delivered as once-daily patches or gel. For convenience, the gel is available in premeasured dose packets or in a pump dispenser. Testosterone patches increase serum testosterone levels to the normal range in 2 to 6 hours. Serum testosterone levels return to baseline 24 hours after patch or gel administration. However, unlike oral or injectable supplements, transdermal testosterone patches applied at bedtime or testosterone gel applied each morning produce physiologic patterns of serum testosterone levels throughout the day. Although these formulations are often described as producing more “natural” hormone levels, the clinical importance of this biochemical effect is unknown.[60]

The original Testoderm brand patch was formulated for scrotal application. Scrotal skin is thinner and has a richer vascular supply than does the skin on the arms or thighs. Therefore, application of Testoderm patches produced excellent absorption of the hormone. However, the patch could detach when the scrotum became damp or moist, when the patient exercised, or if the scrotum was excessively hairy. Due to its inconvenient site of application, the scrotal patch is no longer commercially available in the United States.

For improved convenience, Androderm patches are formulated for application to the upper arms, back, abdomen, or thighs. The addition of absorption enhancers and adhesives has been linked to a higher incidence of contact dermatitis with Androderm patches compared with the original Testoderm scrotal patch or to gel formulations.

When compared to patches, testosterone gel 1% formulation (AndroGel) is applied in much larger doses (5 or 10 g each day) to the skin of the shoulders, upper arms, or abdomen. The hormone is absorbed quickly, within 30 minutes, but several hours may be required for complete absorption of the dose. For this reason, the patient should be reminded to wait at least 2 hours after application before showering. To prevent inadvertent transfer of testosterone gel to others, the patient should thoroughly wash his hands with soap and water after administration of a dose, allow the application site to dry undisturbed for several minutes before dressing or covering it, and ensure that there is no contact with clothing contaminated with the gel by children and female members of the household.[60]

A high-strength testosterone gel (1.62%) formulation is also available. It allows administration of a daily dose with a smaller amount of gel. It should be applied to the shoulder or upper arms.

Dosing

Table 103-4 lists the usual doses for testosterone replacement regimens. Three to 6 months is considered as an adequate treatment trial with a particular dose.[12] Thus, a dose should not be increased until the patient has used one particular dose for at least this time period. The recommended target serum testosterone level is the mid normal range,[11,60] or 450 to 600 ng/dL (15.6-20.8 nmol/L).[60,62] Repeated serum testosterone levels that exceed the normal range or produce adverse effects will necessitate a dosage reduction or increased interval between drug doses. Table 103-7 provides guidance on the timeline for monitoring serum testosterone levels based on the particular testosterone formulation used. After starting treatment, patients should be reassessed in 1 to 3 months. The patient’s libido, mood, and quality of life may improve in 3 to 4 weeks, erectile function may improve in 6 months, but other symptoms of hypogonadism (eg, bone density) may take longer to resolve. If the patient responds to treatment and serum testosterone levels have returned to normal, the patient can be followed up annually. At each visit, the use of a validated self-assessment tool (eg, Androgen Deficiency in Aging Men Questionnaire) can assist the physician in gauging the patient’s response to treatment.[64]

TABLE 103-7

Timing of Serum Testosterone Level Monitoring in Patients on Testosterone Replacement Regimens

When to Monitor Serum Testosterone Levels	
Oral testosterone tablets/capsules	2-3 hours after dose for peak level only.
Intramuscular testosterone cypionate or enanthate Intramuscular testosterone undecanoate	Midpoint of dosing interval or measure trough level right before the fourth dose. Just before each subsequent injection or measure level halfway between 10-week dosing interval.
Transdermal testosterone gel	Depending on the formulation, just before dose in the morning 2-4 weeks after start of therapy or after a dose adjustment.[65]
Transdermal patch	Before the next dose 2 weeks after start of therapy or after a dose adjustment.
Axillary solution	2-8 hours after application and 2 weeks after starting therapy or after a dosage adjustment.
Intranasal testosterone gel	1 month after starting treatment, measure trough level right before a dose
Testosterone subcutaneous implant	3-6 months after implantation, obtain trough level just before next dose

Data from Reference 60.

Once an optimal dose of a patient's testosterone replacement regimen has been established and the patient has received treatment for at least 3 months, the prescriber should consider discontinuing the regimen if the patient's symptoms of hypogonadism show no improvement.[66]

Before initiating any testosterone replacement regimen in patients 40 years and older, patients should be screened for breast cancer, benign prostatic hyperplasia, and prostate cancer. All are testosterone-dependent conditions and theoretically could be worsened by exogenous administration of testosterone. However, no confirmed cases of prostate cancer caused by testosterone supplementation in a hypogonadal patient have been documented.[67] Nevertheless, untreated prostate cancer is a contraindication to androgen supplementation. To screen for prostate disorders, a prostate-specific antigen serum concentration should be obtained, and a digital rectal examination of the prostate performed particularly in men who are 50 years of age or older. These tests are generally repeated at 1-year intervals after treatment is started. Also, since testosterone supplementation has been reported to worsen severe sleep apnea or edema of congestive heart failure, caution should be exercised in using testosterone in patients with these disorders.[12,60]

Other baseline tests that are recommended include hematocrit and liver function tests. These should be repeated 3 and 6 months after the start of a testosterone replacement regimen. If normal, these tests can be repeated annually thereafter. If the hematocrit exceeds 55% (0.55), the testosterone replacement regimen should be withheld to avoid polycythemia and its consequences.

Adverse Effects

Testosterone replacement regimens can cause sodium retention, which can lead to weight gain, or exacerbate hypertension, congestive heart failure, and edema (Table 103-6). Although serum lipoprotein perturbations may occur, testosterone replacement regimens have a neutral effect in that they decrease both total cholesterol and high-density lipoprotein cholesterol levels. Two retrospective studies associated testosterone supplementation with an increased risk of myocardial infarction and stroke.[68,69] Although these studies did not show a cause–effect relationship and are considered inconclusive, the FDA included a labeling warning that testosterone supplementation may lead to cardiovascular disease and physicians should discuss this potential risk with patients before initiating treatment. This was prompted by a significant increase in testosterone use in the United States, inadequate monitoring of serum testosterone levels prior to and during testosterone supplementation, and the potential hazards of using testosterone supplementation in elderly patients with cardiovascular risk factors.[70]

Since then, some prospective clinical trials have documented the safe use of testosterone replacement regimens in patients with risk factors for cardiovascular disease and these were included in a recent meta-analysis.[66,71] Nevertheless, in view of the product labeling, prescribers are advised to discuss the potential risks of testosterone replacement regimens with patients before initiating treatment, and to carefully monitor patients for adverse effects.[62] For patients who have had a myocardial infarction, stroke, or worsening of congestive heart failure, a testosterone replacement regimen should be delayed for at least 6 months.[11,61]

Gynecomastia can occur because of conversion of testosterone to estrogen in peripheral tissues. This has been reported most often in patients with liver cirrhosis or those who are obese.

Oral alkylated testosterone replacement regimens have caused hepatotoxicity, ranging from mild elevations of hepatic transaminases to serious liver diseases, including peliosis hepatis (hemorrhagic liver cysts), hepatocellular and intrahepatic cholestasis, and benign or malignant tumors. For this reason, parenteral or transdermal testosterone replacement regimens are preferred.

Transdermal testosterone patches may cause contact dermatitis, which responds well to topical corticosteroids. This adverse effect has been associated with the presence of permeation enhancers, which are added to patch formulations. If the dermatitis from the patch formulation becomes problematic, testosterone gel is associated with a lower incidence of contact dermatitis.

Erythrocytosis occurs most often in patients receiving parenteral testosterone formulations. If the increase in hematocrit is mild, decreasing the dose of testosterone replacement is all that is needed. However, if the hematocrit exceeds 55% (0.55) testosterone injections should be stopped and can be replaced with a transdermal testosterone product.[60]

Although testosterone supplementation in men with late-onset hypogonadism has not been shown to cause prostate cancer, it should not be given to men with known prostate cancer that has not been treated.[60,72]

Alprostadil

Mechanism

Alprostadil, also known as prostaglandin E_1, stimulates adenyl cyclase, resulting in increased production of cAMP, a secondary messenger that activates protein kinase A, which decreases intracellular calcium concentrations and causes smooth muscle relaxation of the arterial blood vessels and sinusoidal tissues in the corpora. This results in enhanced blood flow to and blood filling of the corpora.[38,51] Because it does not require nitric oxide to produce its clinical effects, patients with erectile dysfunction due to diseases that are associated with an impaired nitric oxide pathway (eg, diabetes mellitus, post radical prostatectomy, patients in whom phosphodiesterase type 5 inhibitors are contraindicated, and patients who fail phosphodiesterase type 5 treatment) may respond to alprostadil.[38,39]

Alprostadil is commercially available as an intracavernosal injection (Caverject and Edex) and as an intraurethral insert (medicated urethral system for erection [MUSE]).

Indications

Both commercially available formulations of alprostadil are FDA approved as monotherapy for management of erectile dysfunction.

The efficacy of the intracavernosal injection may be related to the excellent bioavailability of the drug when injected directly into the corpora cavernosum. In contrast, intraurethral alprostadil doses generally are several hundred times larger than intracavernosal doses. This is because intraurethral alprostadil must be absorbed from the urethra, through the corpus spongiosum, and into the corpus cavernosum, where it exerts its full proerectogenic effect.

Although several other agents, including papaverine and phentolamine, have been used off-label for intracavernosal therapy, alprostadil is preferred. This is because intracavernosal alprostadil has been approved by the FDA for erectile dysfunction, it does not require extemporaneous compounding, and it has a low potential for causing prolonged erections and priapism.

Both formulations of alprostadil are considered more invasive than VEDs or phosphodiesterase type 5 inhibitors. For this reason, intracavernosal alprostadil is generally prescribed after patients do not respond to or cannot use less invasive interventions. Intracavernosal alprostadil is preferred over intraurethral alprostadil because of its greater effectiveness. Intracavernosal alprostadil may be preferred in patients with diabetes mellitus, who are accustomed to injectable drug therapy and may have peripheral neuropathies, which decrease the patient's perception of pain upon injection. Intraurethral alprostadil is generally reserved as a treatment of last resort for patients who do not respond to other less invasive and more effective forms of therapy, and who refuse surgery.

Intracavernosal Alprostadil

Efficacy

The overall efficacy of intracavernosal alprostadil is 70% to 90%.[22] Three characteristics of intracavernosal alprostadil include the following:

1. The effectiveness of alprostadil is dose related. The mean duration of erection is directly related to the dose of alprostadil administered and ranges from 12 to 44 minutes.
2. A higher percentage of patients with psychogenic and neurogenic erectile dysfunction respond to alprostadil at a lower dose compared to patients with vasculogenic erectile dysfunction.
3. Tolerance does not appear to develop with continued use of intracavernosal alprostadil at home.

⑩ Although 70% to 75% of patients respond to intracavernosal alprostadil, a high proportion of patients elect to discontinue its use over time. Depending on the study and the length of observation, 30% to 50% of patients voluntarily discontinue therapy, usually during the first 6 to 12 months, and this increases to 54% and 67% after 2 to 4 years, respectively.[22,38] After 10 years, less than 5% of patients continue intracavernosal injections. Common reasons for discontinuation include lack of perceived effectiveness; inconvenience of administration; an unnatural, nonspontaneous erection; needle phobia; penile pain, loss of interest; or cost of therapy.

Approximately one-third of patients do not respond to usual doses of intracavernosal alprostadil. In these patients, intracavernosal alprostadil has been used successfully along with VEDs. Such combination therapy can be attempted by patients before transitioning to more invasive surgical procedures.[32] Alternatively, intracavernosal injections of synergistic combinations of vasoactive agents that act by different mechanisms have been used. For example, papaverine is a nonspecific phosphodiesterase inhibitor that increases cavernosal concentrations of cAMP and cGMP, and phentolamine is an alpha-adrenergic antagonist that blocks detumescence (thereby prolonging an erection). Intracavernosal drug combinations typically produce an erection that lasts longer than an erection produced by any one of the agents in the mixture. In addition, because of the low dosage of each agent in the combination, fewer systemic and local fibrotic adverse effects develop compared with high-dose monotherapy. For example, when used in low-dose combination regimens, papaverine is less likely to induce hypotension and liver dysfunction, and phentolamine is less likely to induce tachycardia and hypotension.[6,22] However, such intracavernosal drug combinations are not commercially available and must be extemporaneously compounded. Several different two- or three-drug formulations have been used, but no one formulation is considered a standard.[22,32] Finally, intracavernosal alprostadil has been used in combination with phosphodiesterase type 5 inhibitors; however, this use is an unlabeled indication.[22,32]

Pharmacokinetics

Intracavernosal injection should be administered into only one corpus cavernosum. From this injection site, the drug will reach the other corpus cavernosum through vascular communications between the two corpora. Alprostadil acts rapidly, with an onset of 5 to 15 minutes. The duration is directly related to the dose. Within the usual dosage range of 2.5 to 20 mcg, the duration of erection is not more than 1 hour. Higher doses are expected to exhibit a longer duration of action. Local 15-hydroxy dehydrogenase in the corpora cavernosum quickly converts alprostadil to inactive metabolites. Any alprostadil that escapes into the systemic circulation is deactivated on first pass through the lungs. Hence, the plasma half-life of alprostadil is approximately 5 to 10 minutes, and the potential for systemic and local adverse effects is negligible.[22,30] Dose modification is not necessary in patients with renal or hepatic disease.

Dosing

The usual dose of intracavernosal alprostadil is 10 to 20 mcg, with a maximum recommended dose of 60 mcg. Doses greater than 60 mcg have not produced any greater improvement in penile erection but may cause hypotension or prolonged erections lasting more than 1 hour. The dose should be administered 5 to 10 minutes before intercourse. The manufacturer recommends that patients be slowly titrated up to the minimally effective dosage to minimize the likelihood of hypotension. Under a health professional's supervision, patients should be started with a 1.25-mcg dose, which can be increased in increments of 1.25 to 2.50 mcg at 30-minute intervals up to the lowest dose that produces a firm erection for 1 hour and does not produce adverse effects. In clinical practice, this process is rarely done because it is time-consuming.[28] Thus, many physicians start the patient on 10 mcg and move quickly up the dosage range to identify the best dose for the patient. To avoid adverse effects, patients should receive not more than one injection per day and not more than three injections per week with a 24-hour interval between doses (see Table 103-4).

Intracavernosal injections should be performed using a 0.5-in. (1.3 cm), 27- or 30-gauge needle. A tuberculin syringe or a syringe prefilled with diluent as supplied by the manufacturer should be used to ensure precise measurement of doses. Patients with needle phobia, poor vision, or poor manual dexterity can use commercially available autoinjectors to facilitate administration of intracavernosal alprostadil.[30]

Intracavernosal injections require that the patient or the sexual partner practice good aseptic techniques (to avoid infection), have good manual skills and visual ability, and be comfortable with injection techniques. When practicing self-injection, the patient should use one hand to firmly hold the glans penis against his thigh to expose the lateral surface of the shaft. The injection should be made at right angles into one of the lateral surfaces of the proximal third of the penis. The injection should never be made into the dorsal or ventral surface of the penis. This will prevent inadvertent injection of the drug into arteries on the dorsal surface or the urethra on the ventral surface. After the injection, the penis should be massaged to help distribute the drug into the opposite corpus cavernosum. Injection sites should be rotated with each dose. Finally, manual pressure should be applied to the injection site for 5 minutes to reduce the likelihood of hematoma formation (Fig. 103-5).

Once the optimal dosage of intracavernosal alprostadil is established, the patient should return for routine medical follow-up every 3 to 6 months. Some patients subsequently require dosage adjustment, largely attributed to worsening of the underlying disease that is contributing to the erectile dysfunction.

Adverse Effects

Intracavernosal alprostadil is most commonly associated with local adverse effects. Hematoma and bruising at the injection site occur most often during the first year of therapy. These effects are largely the result of poor injection technique. To minimize the risk of injection site hematomas, patients should apply pressure to the injection site for 5 minutes after each dose. Similarly, infection at the injection site has been reported. Meticulous aseptic technique is necessary to prevent this complication.

Cavernosal plaques or areas of fibrosis at injection sites form in approximately 2% to 12% of patients.[51] When they occur, the patient should suspend further injections for 2 to 4 months or until the plaques resolve. These plaques may cause penile curvature, similar to Peyronie's disease, which makes sexual intercourse difficult or impossible. The cause of corporal fibrosis and plaque formation is unknown. This adverse effect may be caused by poor injection technique or by alprostadil itself. Although patients have developed corporal fibrosis, alprostadil may be less likely to cause this adverse effect compared to other intracavernosal drug combinations, such as phentolamine or papaverine. Unlike cavernosal fibrosis associated with large doses and repeated administration of papaverine, penile scarring secondary to alprostadil appears to be unpredictable.

Alprostadil causes penile pain in approximately 10% to 44% of patients. The pain has been described as a burning discomfort or dull pain near the injection site or during the erection, which generally does not persist after the penis becomes flaccid. The pain usually is mild, generally does not require discontinuation of therapy, and often abates even with continued treatment.[22] However, 2% to 5% of patients discontinue taking alprostadil because of severe pain. The pain can be managed by oral analgesics (eg, acetaminophen), if necessary. One investigator has recommended adding procaine to intracavernosal alprostadil, but this may mask the signs of more serious adverse effects of the drug or of penile injury during intercourse, and is not recommended. The mechanism of this adverse reaction is poorly understood. Alprostadil may intrinsically produce pain. In addition, the pain may be a result of the pH of the parenteral solution. Alprostadil is acidic, and the commercially available Caverject formulation is buffered with sodium citrate, a weak base, to reduce pain on injection.[6]

Priapism, a prolonged, painful erection lasting more than 1 hour, occurs in 1% to 15% of treated patients. It occurs most often during the dose titration period and is rare thereafter. Blood sludging in the corpora can lead to tissue hypoxia and irreversible cavernosal fibrosis and scarring. The risk for this complication is greatest for erections that persist beyond 4 to 6 hours. Patients are advised to seek medical attention immediately when drug-induced erections last more than 4 hours, as this may progress to a urologic emergency.[22] Its management includes supportive care, including analgesics for pain and sedatives for anxiety. In addition, needle aspiration of sludged blood in the corpora or intracavernosal injection of α-adrenergic agonists (eg, phenylephrine) has been used. These procedures facilitate venous drainage of the corpora, allowing venous outflow to "catch up" with arterial inflow.[6,30]

The likelihood of prolonged erections with intracavernosal alprostadil is dose related. Therefore, to prevent this adverse effect, the lowest effective dose should be used, and the dose should be titrated to ensure that the duration of the erection is not more than 1 hour.

Intracavernosal alprostadil rarely causes systemic adverse effects, owing to the agent's local catabolism in cavernosal tissue and rapid deactivation in pulmonary tissue (if any of the drug escapes into the systemic circulation). However, large doses greater than 20 mcg are associated with dizziness and hypotension in some patients and is one reason why such large doses are not commonly used.

Intracavernosal injection therapy should be used cautiously by patients at risk for priapism, including patients with sickle cell disease, leukemia, or multiple myeloma. It should be used cautiously by patients who may develop bleeding complications secondary to injections, including patients with thrombocytopenia or those taking anticoagulants. It also should be used cautiously by patients who use poor-quality injection technique, including patients with psychiatric disorders, obese patients (who may not be able to reach or see the penile injection site), patients who are blind, patients with severe arthritis, or patients with abnormal penile anatomy.[22,24]

Intraurethral Alprostadil

Efficacy

⑩ Intraurethral alprostadil inserts are marketed as MUSE, which contains a medication pellet inside a prefilled urethral applicator. Multiple studies show this product has an overall effectiveness rate of 43% to 65%[22] compared with 70% to 90% for intracavernosal alprostadil. Its decreased effectiveness and inconvenient administration method have resulted in this product being considered a second- or third-line treatment option for patients with erectile dysfunction.[67] However, some patients have responded to intraurethral alprostadil even though they did not respond to intracavernosal alprostadil or sildenafil.[73]

Intraurethral alprostadil has been combined with a VED to improve treatment response.[30,32]

The voluntary dropout rate is high and has been reported to be 57% and 75% after 3 and 15 months, respectively.[22] Intraurethral alprostadil should be avoided in patients with urethral stricture or urethritis, or if the female partner is pregnant.

Pharmacokinetics

Following intraurethral instillation, alprostadil is absorbed quickly through the urethra, into the corpus spongiosum, and then into the corpora cavernosum.[24] As much as 80% of each dose is absorbed by the urethra and corpus spongiosum in less than 10 minutes, with peak absorption occurring in 20 to 25 minutes. An estimated 20% of each dose is delivered to the corpora cavernosum. As with intracavernosal injections of alprostadil, any drug absorbed into the systemic circulation is rapidly metabolized on first pass through the lungs.

The onset after intraurethral insertion is similar to that of intracavernosal injection, 5 to 10 minutes, and the duration is 30 to 60 minutes.

Dosing

The usual dosage range of intraurethral alprostadil is 125 to 1,000 mcg, but 500 mcg is typically needed in most patients.[22] It is recommended that the first dose be administered under the supervision of a health professional.[24] The dose should be administered 5 to 10 minutes before sexual intercourse. Not more than two doses per day are recommended. Before administration, the patient should be advised to empty his bladder, voiding completely (see Table 103-4).

Similar to intracavernosal injection treatments, intraurethral insertion of alprostadil requires good manual and visual skills to minimize the risk of urethral injuries. Intraurethral alprostadil is supplied in a prefilled intraurethral applicator. The patient should void first to moisten the urethra. With one hand the patient holds the glans penis, and with the other hand, the patient inserts the intraurethral applicator 0.5 in. (1.3 cm) into the urethra. The drug pellet is then pushed into the urethra. The penis should be massaged to enhance drug dissolution in the urethral fluids and drug absorption (Fig. 103-6).

Adverse Effects

The urethra can be injured because of an improper administration technique. Injuries can lead to urethral bleeding or stricture and difficulty voiding. Patients should receive complete education about optimal administration procedures before starting treatment.

Urethral pain has been reported in 24% to 43% of patients. Usually, it is mild and does not require discontinuation of treatment. Approximately 6% of female sexual partners may experience vaginal burning, itching, or pain, which probably is related to transfer of alprostadil from the man's urethra to the woman's vagina during intercourse.[22,30]

Prolonged painful erections (priapism) have been rarely reported. Syncope and dizziness have been reported rarely (only 2%-3% of patients) and likely are related to use of excessively large doses.

Unapproved Agents

A variety of other commercially available and investigational agents have been used for management of erectile dysfunction. Although it is beyond the scope of this chapter to discuss all of them, some of the more commonly used agents are discussed here.

Yohimbine

Yohimbine, a tree-bark derivative also known as *yohimbe*, is widely used as an aphrodisiac. Yohimbine is a central alpha$_2$-adrenergic antagonistic that increases catecholamines and improves mood. Some investigators believe that yohimbine has peripheral proerectogenic effects. Yohimbine may reduce peripheral alpha-adrenergic tone, thereby permitting a predominant cholinergic tone, which could result in a vasodilatory response.[22,51] The usual oral dose is 6 to 15 mg three times per day.

Based on a meta-analysis of published studies that concluded that yohimbine is only mildly efficacious for psychogenic erectile dysfunction, the American Urological Association has cautioned against the use of yohimbine.[22] In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension.

Papaverine

Papaverine is a nonspecific phosphodiesterase type 5 inhibitor that decreases metabolic catabolism of cAMP in cavernosal tissue. As a result of enhanced tissue levels of cAMP, smooth muscle relaxation occurs. Cavernosal sinusoids fill with blood, and a penile erection results.

Papaverine is not FDA approved for erectile dysfunction. Intracavernosal papaverine alone is not commonly used for management of erectile dysfunction because the large doses required to achieve a therapeutic effect also produce dose-related adverse effects, such as priapism, corporal fibrosis, hypotension, and hepatotoxicity.[22] Papaverine is more often administered in lower doses combined with phentolamine and/or alprostadil. A variety of formulas have been used, but no one mixture has been proven better than other mixtures. Combination formulations are considered safer and are associated with the potential for fewer serious adverse effects than high doses of any one of these agents.

A portion of each papaverine dose is systemically absorbed, and its prolonged plasma half-life of 1 hour contributes to adverse effects. The usual dose of papaverine is 7.5 to 60 mg when used as a single agent for intracavernosal injection. When used in combination, the dose decreases to 0.5 to 20 mg.

If treated with papaverine, patients with a history of underlying liver disease or alcohol abuse should undergo liver function testing at baseline and every 6 to 12 months during continued treatment.

Phentolamine

Phentolamine is a competitive nonselective alpha-adrenergic blocking agent. It reduces peripheral adrenergic tone and enhances cholinergic tone. As a result, it improves cavernosal filling and is proerectogenic.[22]

Phentolamine has most often been administered as an intracavernosal injection. Monotherapy is avoided because large doses are required for an erection, and at these large doses systemic hypotensive adverse effects would be prevalent. Most often, phentolamine has been used in combination with other vasoactive agents for intracavernosal administration. A ratio of 30-mg papaverine to 0.5 to 1 mg phentolamine is typical, and the usual dose ranges from 0.1 to 1 mL of the mixture. Such a mixture minimizes systemic hypotensive adverse effects.

Hypotension is the most common adverse effect of intracavernosal phentolamine. It is more common and more severe with large doses or in patients with a poor injection technique who have injected into a vein (rather than the cavernosa). Prolonged erections have been reported in patients who used excessive doses of intracavernosal medications in combination.

Surgical Therapy

Penile Prostheses

Surgical insertion of a penile prosthesis is the most invasive treatment of erectile dysfunction. It is reserved for patients who do not respond to or who are not candidates for less invasive medical treatments or devices.

Prosthesis insertion requires anesthesia, an operating room, and a skilled urologist. Two prostheses are widely used: malleable and inflatable. Malleable or semirigid prostheses consist of two bendable rods that are inserted into the corpora cavernosa. The patient appears to have a permanent erection after the procedure; the patient is able to bend the penis into position at the time of intercourse.[22,31,74,75]

The inflatable prosthesis has several mechanical parts, including a pump, reservoir, and fillable cylinders. Once it is manually activated, a pump transfers fluid from a reservoir into the cylinders in the corpora cavernosa. The inflatable prosthesis produces a more natural erection, and for this reason, it is associated with a higher patient satisfaction rate than a malleable prosthesis.[72,73] The patient develops an erection only when the device is activated. Inflatable prostheses are available as 2- or 3-piece devices; fewer mechanical parts are associated with fewer malfunctions. With improvements in technology, inflatable devices can be placed during shorter surgical procedures and have a low 10-year mechanical failure rate (5%-15%) as compared with the original inflatable prostheses (Fig. 103-7).[22,74]

FIGURE 103-7

Example of surgically implanted penile prosthesis. (a, activation mechanism; b, reservoir with fluid for inflating prosthesis; c, inflatable rods in corpora.) (*Reprinted from the National Institutes of Health/National Institute of Diabetes and Digestive and Kidney Diseases.*)

Penile prostheses provide penile rigidity suitable for vaginal intercourse and are associated with a greater than 90% patient satisfaction rate, which is generally higher than that observed with any other drug treatment or VED. The surgical success rate after insertion is 82% to 98%.[74]

Adverse effects of prosthesis insertion can occur early or late after the surgical procedure. The most common early complication is infection. Late complications include mechanical failure of the prosthesis, erosion of the rods through the penis, or late-onset infection. Although some salvage procedures have been devised, in many cases the prosthesis requires removal.[75]

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcomes of specific treatments for erectile dysfunction include (a) improvement in the quantity and quality of penile erections suitable for intercourse and (b) avoidance of adverse drug reactions and drug interactions.

At baseline and after the patient has completed a clinical trial period of several weeks with a specific treatment for erectile dysfunction, the physician should conduct assessments to determine whether the quality and quantity of penile erections has improved. A patient's level of satisfaction is highly individualized, depending on his lifestyle and expectations. Therefore, a patient who has successful intercourse once per week might be completely satisfied, whereas another patient might judge this to be unsatisfactory. Patients with unrealistic expectations in this regard must be identified and counseled by clinicians to avoid adverse effects of excessive use of erectogenic agents.

Failure to improve the quality and quantity of penile erections suitable for intercourse after an appropriate clinical trial period with a specific treatment for erectile dysfunction occurs in a significant percentage of patients. In this case, physicians generally take the following steps to:

1. Ensure that the patient has been prescribed a maximum tolerated medication dose and has an adequate clinical trial of a specific treatment before discarding it as ineffective.
2. Switch to another drug (see Fig. 103-2).
3. Reserve surgical treatment for patients who do not respond to drug treatment.

CONCLUSION

Erectile dysfunction is a common disorder of aging men. Its incidence is higher in patients with underlying medical disorders that compromise the vascular, neurologic, hormonal, or psychogenic systems necessary for a normal penile erection. Medications are common causes of erectile dysfunction. By correcting the underlying etiology, erectile dysfunction can often be reversed without the use of specific treatments. When treatment of erectile dysfunction is needed, the least invasive options should be used first because they produce the lowest incidence of serious adverse effects. Phosphodiesterase type 5 inhibitors are first-line treatment. If this fails or if the patient cannot use a phosphodiesterase type 5 inhibitor, a VED or intracavernosal injection or intraurethral alprostadil can be initiated. If this treatment fails, the patient can attempt a combination of intracavernosal alprostadil and VED, combination intracavernosal therapy, or intraurethral alprostadil. If this treatment fails, the patient may require insertion of a penile prosthesis. Some insurance companies do not reimburse for drug treatments for erectile dysfunction, so cost is an important issue for patients. Clinicians should provide clear and simple advice. Patient confidentiality and privacy, which are extremely important to men with erectile dysfunction, should be maintained at all times.

SELF-ASSESSMENT QUESTIONS

1. Which of the following medications for erectile dysfunction would be a good choice for a patient with dysphagia?
   - A. Avanafil tablet
   - B. Tadalafil tablet
   - C. Sildenafil tablet
   - D. Vardenafil ODT
   - E. Testopel implant
2. After taking sildenafil 100 mg, taken on demand on four separate occasions, the patient returns to the physician's office to complain that the medication is not working. His erectile dysfunction has not responded to treatment. The most appropriate action that the physician should take at this time is
   - A. Discontinue sildenafil and switch the patient to a vacuum erection device.
   - B. Switch the patient from on-demand sildenafil to daily sildenafil 10 mg.
   - C. Continue current regimen for a total of 7 to 8 doses and review the instructions for proper use.
   - D. Increase the sildenafil dose to 20 mg and instruct the patient to try this the next time.
   - E. Combine sildenafil 10 mg with intracavernosal alprostadil and instruct the patient to take both on demand.
3. If vardenafil is taken with rifampin, the drug interaction may result in:
   - A. Decreased efficacy of vardenafil
   - B. Priapism
   - C. Increased blood pressure
   - D. Acute hearing loss
   - E. Nausea and vomiting

4. Which one of the following statements about phosphodiesterase type 5 inhibitors is correct?

   A. If a patient is taking doxazosin, blood pressure should be stabilized before starting the phosphodiesterase type 5 inhibitor.

   B. If the patient has taken a nitrate, all phosphodiesterase type 5 inhibitors should be held for at least 1 week.

   C. Sildenafil prolongs the QT interval in patients taking quinidine or procainamide.

   D. The combination of erythromycin and a phosphodiesterase type 5 inhibitor will result in severe coughing.

   E. The combination of a phosphodiesterase type 5 inhibitor and intracavernosal alprostadil will likely result in hypotension.

5. If a patient develops an acute, painless loss of vision in one eye while taking sildenafil 100 mg on demand, the most appropriate counseling information is

   A. Discontinue sildenafil and do not start another phosphodiesterase type 5 inhibitor.

   B. Discontinue sildenafil and start vardenafil.

   C. Discontinue sildenafil and start tadalafil.

   D. Continue sildenafil 100 mg on demand.

   E. Continue sildenafil but reduce dose to 50 mg on demand.

6. Which one of the following statements about intracavernosal alprostadil is correct?

   A. Alprostadil inhibits adenylate cyclase and increases the level of epinephrine in cavernosal tissue.

   B. It has a low potential to produce systemic adverse effects.

   C. Alprostadil should always be combined with other erectogenic drugs.

   D. When administering a dose, both sides of the corpora cavernosa must be injected with alprostadil.

   E. When administering a dose, alprostadil should be injected into an arm vein.

7. Which one of these testosterone supplements is most often associated with hepatotoxicity?

   A. Oral alkylated testosterone tablets

   B. Transdermal testosterone gel

   C. Intranasal testosterone gel

   D. Transdermal testosterone patch

   E. Testosterone undecanoate injections

8. Which one of these testosterone supplements must be administered at a facility with a REMS program?

   A. Transdermal testosterone gel

   B. Intranasal testosterone gel

   C. Oral alkylated testosterone tablets

   D. Testosterone undecanoate injections

E. Testosterone enanthate injections

9. Which one of the following adverse effects of testosterone supplements necessitates discontinuing its use?

   A. Azoospermia

   B. Hematocrit of 55% (0.55)

   C. Gynecomastia

   D. Serum creatinine of 2 mg/dL (177 µmol/L)

   E. Doubling of ALT and AST over baseline

10. When should the Princeton Consensus Panel guidelines be used?

    A. To assess patients for cardiac side effects of phosphodiesterase type 5 inhibitors

    B. To identify patients who can be treated safely with medications for erectile dysfunction

    C. To monitor a patient’s therapeutic response to alprostadil

    D. To assess the severity of a patient’s erectile dysfunction

    E. To diagnose the type of sexual dysfunction that a patient has

11. Which one of the following statements about the phosphodiesterase type 5 inhibitors–nitrate interaction is correct?

    A. Transdermal nitrates can be used safely with phosphodiesterase type 5 inhibitors.

    B. When compared to vardenafil, tadalafil has less potential to interact with nitrates.

    C. All nitrates by any route of administration are contraindicated in a patient taking any phosphodiesterase type 5 inhibitor.

    D. The interaction produces dry mouth, constipation, and decreased sweating.

    E. If taken in low enough doses, phosphodiesterase inhibitors will not interact with nitrates.

12. Which one of the following drugs commonly causes erectile dysfunction?

    A. Nifedipine

    B. Enalapril

    C. Nebivolol

    D. Hydrochlorothiazide

    E. Irbesartan

13. Which of the following statements about VED’s is correct?

    A. VED is only available with a prescription.

    B. Penile pain is a common reason why patients cannot tolerate its use and discontinue use after a few attempts.

    C. A rubber ring may be applied to the erect penis to prolong the erection.

D. Prior to activating the VED, lidocaine jelly should be applied to the penis.

E. A male patient with severe arthritis of both hands is a contraindication to VED use.

14. Which statement about Caverject is correct?

A. An excessive dose may result in priapism.

B. It works by decreasing intracavernosal production of cAMP.

C. It is considered first-line treatment of erectile dysfunction.

D. Pulmonary oil embolism has been associated with its use.

E. Multiple doses during the day can be given.

15. Which one of the following statements is correct about phosphodiesterase type 5 inhibitors used for the treatment of erectile dysfunction?

A. They are 100% effective in all patients.

B. They improve libido, and correct erectile dysfunction and ejaculation disorders.

C. Sildenafil exhibits no significant drug–food interactions.

D. They enhance sexual performance in patients with normal erectile function.

E. Patients should take no more than one dose per day.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Vardenafil ODT is an oral dispersible tablet formulation of vardenafil. It is considered convenient to use because it does not require that the patient swallow the tablet or take it with water. Instead, it dissolves quickly in the patient's saliva when put on the tongue. It ideal for patients with dysphagia.

2. **C.** A minimum clinical trial of a particular dosing regimen of a phosphodiesterase inhibitor is 7 to 8 doses. Therefore, the most prudent course is to allow the patient to have a minimal clinical trial with one dosing regimen before increasing the dose, switching to another phosphodiesterase type 5 inhibitor, or switching to another treatment for erectile dysfunction.

3. **A.** Vardenafil principally is metabolized to inactive metabolites by hepatic CYP3A4 enzymes. Therefore, rifampin, a CYP3A4 inducer would be expected to enhance vardenafil's catabolism and decrease sildenafil's efficacy.

4. **A.** Both doxazosin, an alpha-adrenergic antagonist, and phosphodiesterase type 5 inhibitors can decrease blood pressure. Therefore, it is recommended that a patient's blood pressure should be stabilized on doxazosin before starting a phosphodiesterase 5 inhibitor.

5. **D.** Nonarteritic anterior ischemic optic neuropathy presents as a sudden painless loss of vision in one eye. Although a cause–effect relationship has not been established between phosphodiesterase type 5 inhibitors and NAION, there is an association. Because there is an increased risk of NAION in the fellow eye, the manufacturer recommends discontinuation of the phosphodiesterase type 5 inhibitor if NAION is suspected, and not rechallenging with a phosphodiesterase type 5 inhibitor.

6. **C.** Intracavernosal alprostadil has a low potential to cause systemic side effects because it is catabolized by enzymes in the corpora cavernosa. This treatment is considered second-line treatment for management of erectile dysfunction.

7. **A.** Oral alkylated testosterone formulations, for example, fluoxymesterone, should be avoided as they may cause peliosis hepatis, hepatocellular and intrahepatic cholestasis, and benign and malignant liver tumors.

8. **D.** Testosterone undecanoate may cause severe allergic reactions and pulmonary oil embolism. For this reason, it must be administered at a facility

with a REMS program.

9. **B.** A severely increased hematocrit may lead to polycythemia and its sequelae, including hypertension, thrombosis, vertigo, tinnitus, and other neurologic symptoms.

10. **B.** The Princeton Consensus Panel guidelines identify patients who can and cannot safely engage in sexual activity. Therefore, it identifies patients who can be safely treated with medications for erectile dysfunction.

11. **C.** Because of the potential for severe hypotension when nitrates and phosphodiesterase type 5 inhibitors are taken together, any nitrate by any route of administration is contraindicated when a patient is taking a phosphodiesterase type 5 inhibitor.

12. **D.** Thiazide diuretics are one of the most common causes of erectile dysfunction, whereas angiotensin II antagonists, angiotensin converting enzyme inhibitors, and certain beta-adrenergic antagonists are considered safer antihypertensive agents to use in sexually active male patients.

13. **C.** Once the vacuum erection device pulls blood into the corpora cavernosa, the erection can be maintained by threading a rubber ring on to the base of the penis. The maximum duration that the rubber ring should remain on the penile shaft is 30 minutes.

14. **B.** Caverject or alprostadil works by stimulating adenyl cyclase, which increases production of cAMP, a vasodilatory neurotransmitter in the corpora cavernosa. Excessive doses can result in priapism.

15. **E.** The daily dose of phosphodiesterase type 5 inhibitor should be limited to one dose per day in order to prevent priapism.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 104: Benign Prostatic Hyperplasia

Mary Lee; Roohollah Sharifi

KEY CONCEPTS

KEY CONCEPTS

① Although symptomatic benign prostatic hyperplasia (BPH) is rare in men younger than 50 years, it is common in men aged 60 years and older. Prostate growth is androgen-dependent. Symptoms commonly result from both static and dynamic factors.

② BPH symptoms may be exacerbated by medications, including antihistamines, phenothiazines, tricyclic antidepressants, and anticholinergic agents. In these cases, discontinuing the causative agent can relieve symptoms.

③ For patients with mild disease who are asymptomatic or have mildly bothersome symptoms and no complications of BPH disease, watchful waiting is indicated. Watchful waiting includes behavior modification, lifestyle modification, discontinuation of medications that contribute to voiding symptoms, and return visits to the physician at 6- or 12-month intervals for assessment of worsening symptoms or signs of bladder outlet obstruction.

④ If symptoms progress to a moderate or severe level, drug therapy or surgery is indicated. α_1-Adrenergic antagonists quickly relieve voiding symptoms, but do not prevent disease progression. 5α-Reductase inhibitors delay symptom progression and reduce the incidence of BPH-related complications in patients with prostates of at least 30 to 40 g, but may not reduce voiding symptoms for 3 to 6 months.

⑤ All α_1-adrenergic antagonists are equally effective in relieving BPH symptoms. Older second-generation immediate-release formulations of α_1-adrenergic antagonists (eg, terazosin, doxazosin) can cause adverse cardiovascular effects, mainly first-dose syncope, orthostatic hypotension, and dizziness. For patients who cannot tolerate these hypotensive adverse effects, a third-generation, pharmacologically uroselective α_{1A}-adrenergic antagonist (eg, tamsulosin, silodosin) or an extended-release formulation of alfuzosin, a second-generation, functionally uroselective agent, is a good alternative.

⑥ 5α-Reductase inhibitors are useful primarily for patients with large prostates greater than 40 g who wish to avoid surgery and cannot tolerate the side effects of α_1-adrenergic antagonists. 5α-Reductase inhibitors have a slow onset of action, taking up to 6 months to exert maximal clinical effects, which is a disadvantage of their use, especially as single-drug therapy for BPH. In addition, decreased libido, erectile dysfunction, and ejaculation disorders are common adverse effects, which may be troublesome in sexually active patients.

⑦ Phosphodiesterase type 5 inhibitors can be used in patients with moderate-to-severe BPH and erectile dysfunction. They improve obstructive and irritative voiding symptoms, but do not significantly increase urinary flow rate or reduce postvoid residual (PVR) urine volume. Hence, a phosphodiesterase type 5 inhibitor is considered less effective than an α-adrenergic antagonist for BPH. A phosphodiesterase type 5 inhibitor may be used alone; however, symptom improvement and an increase in peak urinary flow rate have been demonstrated when it is used along with an α-adrenergic antagonist or a 5α-reductase inhibitor.

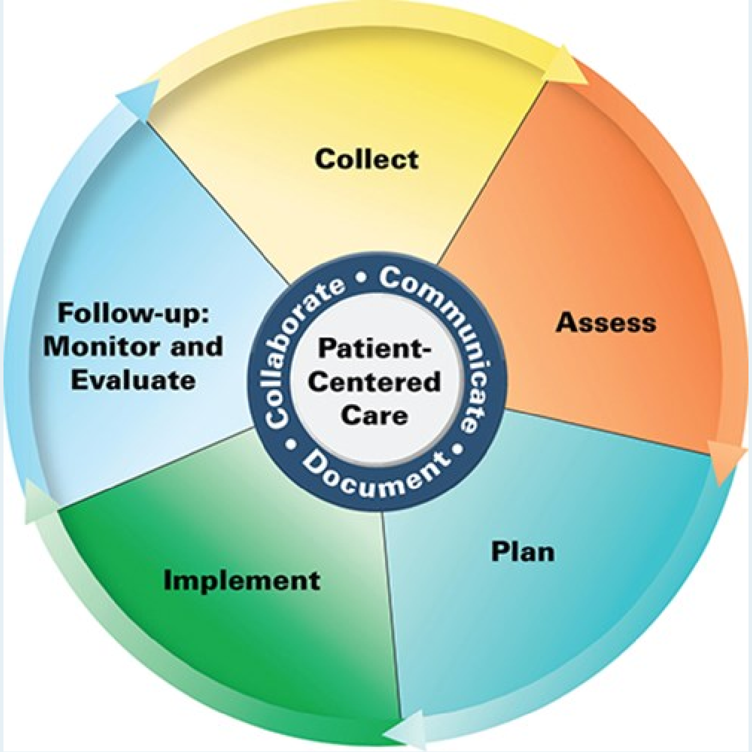
⑧ Anticholinergic agents are indicated in patients with moderate-to-severe lower urinary tract symptoms (LUTS) with a predominance of irritative voiding symptoms. In this case, the drugs are commonly added to an existing regimen of an α_1-adrenergic antagonist or a 5α-reductase inhibitor. Because older patients are at high risk of systemic and central nervous system anticholinergic adverse effects, uroselective anticholinergic agents or those with a low potential to cross the blood brain barrier are preferred over nonuroselective agents. To minimize the risk of acute urinary retention, anticholinergics should be used cautiously in patients when baseline PVR urine volume is greater than 100 to 150 mL. In addition, the anticholinergic medication burden should be assessed by examining the patient's medication profile before starting an anticholinergic agent.

⑨ β_3-Adrenergic agonists relax the detrusor muscle to increase the bladder's storage capacity and prolong the interval between voidings. These medications are indicated for treatment of overactive bladder symptoms, including urgency and nocturia, which mimic irritative lower urinary tract voiding symptoms. Thus, a β_3-adrenergic agonist is an alternative to an anticholinergic agent in patients with irritative voiding symptoms that do not respond to α_1-adrenergic antagonists or in patients who cannot tolerate anticholinergic adverse effects.

⑩ Surgery is indicated for severe symptoms of BPH for patients who do not respond to or do not tolerate drug therapy, or for patients with complications of BPH. It is the most effective mode of treatment because it relieves symptoms and increases peak urinary flow rate in the greatest number of men with BPH. However, the two conventional techniques, transurethral resection of the prostate (TURP) and open prostatectomy, are associated with the highest rates of complications, including retrograde ejaculation and erectile dysfunction. Moreover, because medications are first-line treatment for patients with moderate-to-severe symptoms of BPH, patients who are surgical candidates are often older and more frail. Therefore, minimally invasive surgical procedures are often sought by patients and urologists. Such procedures relieve symptoms and are associated with a lower rate of adverse effects and do not require hospitalization, but they have higher reoperation rates than the standard procedures.

PATIENT CARE PROCESS

Patient Care Process for Benign Prostatic Hyperplasia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race)

- Patient history (past medical history, family history, social—tobacco, recreational drug, or alcohol use)
- Presence of bladder symptoms that are obstructive (slow urinary stream, intermittency, hesitancy, straining to urinate, incomplete emptying, dribbling) and/or irritative (urgency, frequency, nocturia) (see Clinical Presentation box)
- Patient's perception of bothersomeness of voiding symptoms using American Urological Association (AUA) Symptom Score (see Diagnostic Evaluation section)
- Current and past medications, including prescription and nonprescription medications or nonpharmacologic interventions for BPH and medications perceived as causing BPH (see Medication-Related Symptoms section)
- Objective data (see Diagnostic Evaluation section and Clinical Presentation box)
  - BP, heart rate (HR), height, weight, and body mass index (BMI)
  - Digital rectal examination
  - Labs (eg, urinalysis, blood urea nitrogen, serum creatinine, prostate-specific antigen)
  - Urinary flow rates and postvoid residual volume

Assess

- Disease severity (see Table 104-1); patient's views on watchful waiting (in mild cases), medical treatment (in moderate-to-severe cases), and surgery (in severe cases)
- Need for further evaluation based on laboratory and examination findings
- Size of prostate by digital rectal exam or transrectal ultrasound of the prostate
- Presence of BPH, prostate cancer, prostatitis, all of which can cause lower urinary-tract symptoms (LUTS)

Plan*

- Dietary and lifestyle modifications to avoid problematic symptoms and situations (see Medication-Related Symptoms section and Clinical Presentation box)
- Interventions as indicated to encourage heart-healthy lifestyle, smoking cessation, weight loss if needed, management of other chronic diseases
- Drug therapy regimen including specific agent(s), dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Fig. 104-2 and Tables 104-2, 104-3, and 104-4), advantages or disadvantages of single drug versus combination therapy
- Monitoring parameters including efficacy (symptom relief) and safety (medication-specific adverse effects) (see Table 104-5)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy)
- Comparison of during treatment responses by repeating AUA Symptom Score or using a voiding diary (see Diagnostic Evaluation section)
- Referrals to other providers when appropriate (eg, physician, urologist)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence

- Schedule follow-up

Follow-up: Monitor and Evaluate

- Determine BPH goal attainment
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information

*Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Go to a reference text on anatomy and physiology and review the section on the biological male genitourinary tract. Draw a diagram of these organs that shows the anatomical relationship of the kidneys, ureters, urinary bladder, prostate, urethra, and testicles. Then explain how an enlarged prostate could cause obstruction of urinary outflow from the bladder and lead to overflow incontinence, recurrent urinary tract infection, and renal failure.

INTRODUCTION

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm of American men. A nearly ubiquitous condition among elderly men, BPH is of major societal concern, given the large number of men affected, the progressive nature of the condition, and the healthcare costs associated with it. This chapter discusses BPH and its available treatments: watchful waiting, α_1-adrenergic antagonists, 5α-reductase inhibitors, phosphodiesterase inhibitors, anticholinergic agents, β_3-adrenergic agonist, and surgery. The limitations of phytotherapy are described.

Editors' note: In this and other chapters in Pharmacotherapy*, references to biologic gender (as assigned at birth) are used based on prior literature being discussed or anatomical or physiologic differences. We recognize that not all individuals identify with their gender at birth, and to the degree possible when discussing therapeutics, we avoid use of references to gender. In this chapter, gender is used in discussing prior studies, published guidelines, and other recommendations for diagnosis and treatment based on biological gender and does not necessarily reflect an individual's gender identity.*

EPIDEMIOLOGY

According to the results of autopsy studies, approximately 80% of older men develop histologic evidence of BPH. About half of the patients with microscopic changes develop an enlarged prostate gland, and as a result, they may develop symptoms including difficulty emptying urine from the urinary bladder. Approximately half of symptomatic patients eventually require treatment. Thus, the disease can be characterized by three stages: Benign prostatic hyperplasia (BPH), benign prostatic enlargement (BPE), and benign prostatic obstruction (BPO). While BPH itself may not require treatment, some patients with BPE, depending on the size of the prostate, will be at risk of developing complications of BPH. In these patients, 5α-reductase inhibitors can reduce disease complications and delay the need for prostate surgery. In patients with moderate-to-severe BPO, bothersome voiding symptoms require medical or surgical treatment.

① The peak incidence of clinical BPH occurs between ages 63 and 65 years. Symptomatic disease is uncommon in men younger than 50 years, but some urinary voiding symptoms are present by the time men reach 60 years of age. The Boston Area Normative Aging Study estimated that the cumulative incidence of clinical BPH was 78% for patients at age 80 years.[1] Similarly, the Baltimore Longitudinal Study of Aging projected that approximately 60% of men at least 60 years old develop clinical BPO.[2]

NORMAL PROSTATE PHYSIOLOGY

Located anterior to the rectum, the prostate is a small heart-shaped, chestnut-sized gland located below the urinary bladder. It surrounds the proximal urethra like a doughnut.

Soft, symmetric, and mobile on palpation, a normal prostate gland in an adult man weighs 15 to 20 g. Physical examination of the prostate must be done by digital rectal examination during which the prostate is manually palpated by inserting a finger into the rectum. Thus, the prostate is examined through the rectal wall.

The prostate gland comprises three layers: an innermost transition zone, a middle central zone, and an outermost peripheral zone.

The prostate has two major functions: (a) to secrete fluids that make up a portion (20%-40%) of the ejaculate volume and (b) to provide secretions with antibacterial effect possibly related to its high concentration of zinc.

ETIOLOGY

The etiologies of BPH include: (a) patient age of 40 years or more; (b) the stimulatory effect of androgens; (c) increased α-adrenergic tone in smooth muscle of the prostate and prostatic urethra; and (d) chronic inflammation of the prostate.

Patient Age of 40 Years or More

At birth, the prostate is the size of a pea and weighs approximately 1 g. The prostate remains that size until the boy reaches puberty. At that time, the prostate undergoes its first growth spurt, growing to its normal adult size of 15 to 20 g by the time the man is 25 to 30 years old. The prostate remains this size until the patient reaches the age of 40 years, when a second growth spurt begins and continues for the rest of his lifetime. During this second growth spurt, BPE develops.[3]

Stimulatory Effect of Androgens and Increased α-Adrenergic Tone

The prostate gland comprises three types of tissue: epithelial tissue, stromal tissue, and the capsule. Epithelial tissue, also known as *glandular tissue*, produces prostatic secretions. These secretions are delivered into the urethra during ejaculation and contribute to the total ejaculate volume. Androgens stimulate epithelial tissue growth. Stromal tissue, also known as *smooth muscle tissue*, is embedded predominantly with α_1-adrenergic receptors, predominately of the α_{1A} subtype. Stimulation of these receptors by norepinephrine causes smooth muscle contraction, which results in an extrinsic compression of the urethra, reduction of the urethral lumen, and decreased urinary bladder emptying. The normal prostate is composed of a higher amount of stromal tissue than epithelial tissue, as reflected by a stromal-to-epithelial tissue ratio of 2:1. This ratio is exaggerated to 5:1 for patients with BPH, which explains why α_1-adrenergic antagonists are quickly effective for symptomatic management and why 5α-reductase inhibitors reduce an enlarged prostate gland by only 25%.[3] The capsule, or outer shell of the prostate, is composed of fibrous connective tissue and smooth muscle, which also is embedded with α_1-adrenergic receptors. When stimulated with norepinephrine, the capsule contracts around the prostatic urethra (Fig. 104-1).

Testosterone is the principal testicular androgen in males, whereas androstenedione is the principal adrenal androgen. These two hormones are responsible for penile and scrotal enlargement, increased muscle mass, and maintenance of the normal male libido. These androgens are converted by 5α-reductase in target cells to dihydrotestosterone (DHT), an active metabolite. Two types of 5α-reductase exist. Type I enzyme is localized to sebaceous glands in the frontal scalp, liver, and skin, although a small amount is in the prostate. DHT produced at these target tissues causes acne and increased body and facial hair. Type II enzyme is localized to the prostatic stroma, genital tissue, and hair follicles of the scalp. In the prostate, DHT induces growth and enlargement of the gland.[3]

In prostate cells, DHT has greater affinity for intraprostatic androgen receptors than testosterone, and DHT forms a more stable complex with the androgen receptor. Thus, DHT is considered a more potent androgen than testosterone in the prostate. Of note, despite the decrease in testicular androgen production in the aging male, intracellular DHT levels in the prostate remain normal, probably due to increased activity of intraprostatic 5α-reductase.[4]

Estrogen, a product of peripheral metabolism of androgens, is believed to stimulate the growth of the stromal portion of the prostate gland. Estrogens are produced when testosterone and androstenedione are converted by aromatase enzymes in peripheral adipose tissues.[4] In addition, estrogens may induce the androgen receptor.[2] As men age, the ratio of serum levels of testosterone to estrogen decreases as a result of a decline in testosterone production by the testes and increased adipose tissue conversion of androgen to estrogen.

Chronic Inflammation of the Prostate

Chronic inflammation stimulates stromal cell growth in the prostate. In addition, inflammation causes cytokine release, which stimulates glandular epithelial tissue proliferation and transition zone enlargement. Proposed triggers for chronic inflammation include dyslipidemia, low serum testosterone, and hyperestrogenism, which have all been associated with metabolic syndrome, a common disorder of aging men and those with

BPH.[5–7]

PATHOPHYSIOLOGY

Although the precise pathophysiologic mechanisms causing BPH remain unclear, the role of intraprostatic DHT and type II 5α-reductase in the development of BPH is evidenced by several observations:

1. BPH does not develop in men who are castrated before puberty.
2. Patients with type II 5α-reductase enzyme deficiency do not develop BPH.
3. Castration causes an enlarged prostate to shrink.
4. Administration of testosterone to orchiectomized dogs of advanced age produces BPH.

The pathogenesis of BPH is often described as resulting from both static and dynamic factors. Static factors relate to anatomic enlargement of the prostate gland, which produces a physical block at the bladder neck and thereby obstructs urinary outflow. Enlargement of the gland depends on androgen stimulation of epithelial tissue and estrogen stimulation of stromal tissue in the prostate. Dynamic factors relate to excessive α-adrenergic tone of the stromal component of the prostate gland, bladder neck, and posterior urethra, which results in contraction of the prostate gland around the urethra and narrowing of the urethral lumen.[5,7]

Obstructive voiding symptoms of BPH disease, which include decreased force of the urinary stream and incomplete bladder emptying, may result from static and/or dynamic factors, and this must be recognized when drug therapy is considered. For instance, some patients may present with obstructive voiding symptoms, but have prostates of normal size. In these patients, dynamic factors likely are responsible for the symptoms. However, for patients with enlarged prostate glands, static and dynamic factors likely are working in concert to produce the observed symptoms. Moreover, the likelihood of developing moderate-to-severe obstructive voiding symptoms is directly related to the increasing size of the prostate gland.[5,7]

Dynamic factors may be accentuated if the patient becomes stressed or is in pain. In these situations, increased α-adrenergic tone may precipitate excessive contraction of prostatic stromal tissue. When the stressful event resolves, voiding symptoms often improve.[2]

Irritative voiding symptoms of BPH disease, which include urinary frequency and urgency, result from long-standing bladder outlet obstruction. As BPH progresses, the bladder muscle undergoes hypertrophy so that it can generate a greater contractile force to empty urine past the anatomic obstruction at the bladder neck. Decompensation eventually occurs and the hypertrophied bladder muscle is no longer able to generate adequate contractile force; the bladder becomes ineffective in emptying urine. Acute urinary retention, recurrent urinary tract infections, and renal failure complicate progressive, untreated disease.[8]

MEDICATION-RELATED SYMPTOMS

② Medications in several pharmacologic categories should be avoided for patients with BPH because they may exacerbate symptoms. Testosterone replacement regimens, used to treat primary or secondary hypogonadism, deliver additional substrate that can be metabolized to DHT by the prostate. Although no cases of BPH have been reported because of exogenous testosterone administration, cautious use is advised for older patients with prostatic enlargement. α-Adrenergic agonists, used as oral or intranasal decongestants (eg, pseudoephedrine, ephedrine, or phenylephrine), can stimulate α-adrenergic receptors in the prostate, resulting in muscle contraction. By decreasing the caliber of the urethral lumen, bladder emptying may be compromised. β-Adrenergic agonists (eg, terbutaline) may cause relaxation of the bladder detrusor muscle, which prevents bladder emptying.[6] Drugs with significant anticholinergic adverse effects (eg, antihistamines, phenothiazines, tricyclic antidepressants, or anticholinergic drugs used as antispasmodics or to treat Parkinson's disease) may decrease contractility of the urinary bladder detrusor muscle. For patients with BPH who have a narrowed urethral lumen, loss of effective detrusor contraction could result in acute urinary retention, particularly for patients with significantly enlarged prostate glands and a PVR urine volume greater than 150 mL. Diuretics, particularly in large doses, can produce polyuria, which may present as urinary frequency, similar to that experienced by patients with BPH.[8]

CLINICAL PRESENTATION

Patients with BPH can present with a variety of symptoms and signs of disease. All symptoms of BPH can be divided into two categories: obstructive and irritative.

Obstructive symptoms, also known as *prostatism* or *bladder outlet obstruction*, result when dynamic and/or static factors reduce bladder emptying. The force of the urinary stream becomes diminished, urinary flow rate decreases, and bladder emptying is incomplete and slow. Patients report urinary hesitancy and straining and a weak urine stream. Urine dribbles out of the penis, and the urinary bladder always feels full, even after patients have voided. Some patients state that they need to press on their bladder to force out the urine. In severe cases, patients may go into urinary retention when bladder emptying is not possible. In these cases, suprapubic pain can result from bladder overdistension.

Approximately 50% to 80% of patients have irritative voiding symptoms, which typically occur late in the disease course. Irritative voiding symptoms include urinary frequency and urgency. Patients may report waking up every 1 to 2 hours at night to void (nocturia), which significantly reduces quality of life.

Symptoms of BPH vary over time. Symptoms may improve, remain stable, or worsen spontaneously. Thus, BPH is not necessarily a progressive disease; approximately 85% of patients with BPH have stable symptoms when evaluated 4 years after initial diagnosis.[8] Between one-third and two-thirds of men with mild disease stabilize or improve without treatment over 2.5 to 5 years.[2,9] However, worsening symptoms and complications of BPH develop in patients, particularly those with a prostate gland volume greater than 30 to 40 mL or PSAs of 1.4 ng/mL (mcg/L) or greater.[2,9] A patient with a prostate volume of 30 mL or more is three times more likely to develop acute urinary retention.

Collectively, obstructive and irritative voiding symptoms and their negative impact on a patient’s quality of life are referred to as *lower urinary tract symptoms* (LUTS). However, LUTS is not pathognomonic for BPH and may be caused by other diseases, such as neurogenic bladder or urinary tract infection.[2]

Another presentation of BPH is silent prostatism. Patients have LUTS but adapt to the symptoms and do not voluntarily complain about them. Such patients do not present for medical treatment until complications of BPH disease arise or a spouse brings in the symptomatic patient for medical care.

When BPH progresses, it can produce complications that include the following:

1. Acute, painful urinary retention, which can lead to acute renal failure.
2. Persistent or intermittent gross hematuria when tissue growth exceeds its blood supply.
3. Overflow urinary incontinence or unstable bladder.
4. Recurrent urinary tract infection that results from urinary stasis.
5. Bladder diverticula.
6. Bladder stones.
7. Chronic renal failure from long-standing bladder outlet obstruction.

Approximately 17% to 20% of patients with symptomatic BPH require treatment because of disease complications.[7] Men older than 70 years with large prostates of more than 40 g and a PVR urine volume greater than 100 mL are three times more likely to have severe symptoms or suffer from acute urinary retention and to require prostatectomy than patients with smaller prostates. Thus, a serum PSA level of 1.4 ng/mL (mcg/L) or greater has been used as a surrogate marker for an enlarged prostate gland to identify patients at risk for developing complications of BPH disease and has been used to guide selection of the most appropriate treatment modality in some patients.[9]

DIAGNOSTIC EVALUATION

Because the obstructive and irritative voiding symptoms associated with BPH are not unique to the disease and can be presenting symptoms of other genitourinary tract disorders, including prostate or bladder cancer, neurogenic bladder, prostatic calculi, or urinary tract infection, the patient presenting with signs and symptoms of BPH must be thoroughly evaluated.

A careful medical history should be taken to ensure that a complete listing of symptoms is collected to identify concomitant disorders that may be contributing to voiding symptoms. The medical history should be followed by a thorough medication history, including all prescription and nonprescription medications and dietary supplements that the patient is taking. Any drugs that could be causing or exacerbating the patient’s symptoms should be identified. If possible, the suspected drugs should be discontinued or the dosing regimen modified to ameliorate the voiding symptoms.

The patient should undergo a physical examination, including a digital rectal examination, although the size of the prostate gland may not correspond to symptoms. Some patients have only a slightly enlarged gland and yet have bothersome or even serious voiding difficulties. Other patients have intravesical enlargement of the prostate gland (ie, the gland grows into the urinary bladder and produces a ball-valve blockage of the bladder neck). This type of prostate enlargement is not palpable on digital examination.

The patient’s perception of the severity of BPH symptoms guides selection of a particular treatment modality in a patient. To evaluate the patient’s perceptions objectively, validated instruments, such as the AUA Symptom Score (Table 104-1), are commonly used. Using this tool, the patient rates the “bothersomeness” of seven obstructive and irritative voiding symptoms.[9] A patient’s perception of bothersomeness is often based on how much these symptoms interfere with daily activities or cause worry or embarrassment in social settings. Each item is rated for severity on a scale from 0 to 5, such that 35 is the maximum score and is consistent with the most severe symptoms. Patients usually are stratified into the three groups shown in the table based on disease severity for the purposes of deciding a treatment approach.

TABLE 104-1

Categories of BPH Disease Severity Based on Symptoms and Signs

Disease Severity	AUA Symptom Score[a]	Typical Symptoms and Signs
Mild	≤7	• Asymptomatic • Peak urinary flow rate ≥10 mL/s • PVR urine volume ≤25-50 mL≻≺
Moderate	8-19	• Peak urinary flow rate <10 mL/s • PVR urine volume >25-50 mL • Plus obstructive voiding symptoms and irritative voiding symptoms (signs of detrusor instability)
Severe	≥20	All of the above plus 1 or more complications of BPH[a]

[a]Score range, 0-35.

AUA, American Urological Association; BPH, benign prostatic hyperplasia; BUN, blood urea nitrogen; PVR, postvoid residual urine volume.

In addition, the patient can complete a voiding diary in which he records the number of voids, the volume of each void, and voiding symptoms each day for several days. This information is used to evaluate symptom severity and tailor recommendations for lifestyle modifications that may ameliorate symptoms.

The only clinical laboratory test that must be performed is a urinalysis. Because many of the voiding symptoms of BPH could be caused by other urologic disorders, a urinalysis can help screen for hematuria, urolithiasis, and infection. To screen for prostate cancer, another common cause of glandular enlargement, a PSA test may be performed for patients aged 40 years or more, with at least a 10-year life expectancy, in whom the potential benefit of diagnosing the disorder will be outweighed by the cost of the test.[9]

Objective measures of bladder emptying include peak and average urinary flow rate (normal is at least 10 mL/s). These measures are determined using an uroflowmeter, which checks the rate of urine flow out of the bladder. This is a quick noninvasive outpatient procedure in which the patient is instructed to drink water until his bladder feels full and then the patient's urinary flow is clocked during voiding. A low urinary flow rate (<10-12 mL/s) implies failure of bladder emptying due to obstruction or a functional disorder of the detrusor muscle. A patient with such a low urinary flow rate has a fourfold greater risk of acute urinary retention than patients with higher urinary flow rates.[5,7]

Another objective measure is PVR urine volume (normal is 0 mL), which is assessed using abdominal ultrasonography. A PVR urine volume of 25 to 50 mL or more implies failure of bladder emptying and a predisposition for urinary tract infections, whereas a PVR of 100 mL or more has been associated with progressive worsening of BPH symptoms if no specific treatment is initiated.[10]

Because of a weak correlation among voiding symptoms, prostate size, and urinary flow rate, most physicians use a combination of measures, including the patient's assessment of symptoms along with objective evaluation of urinary outflow, PVR, and presence of complications of BPH to determine the need for treatment.

Many other tests can be performed if additional information is needed to assess the severity of BPH disease and its complications, to assist in the preoperative assessment of the patient, or to distinguish prostate enlargement due to BPH from that caused by prostate cancer. Tests include a serum BUN and creatinine, voiding cystometrogram, transrectal ultrasound of the prostate, IV pyelogram, renal ultrasound, and prostate biopsy.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Benign Prostatic Hyperplasia

General

- A patient is in no acute distress unless he has moderate-to-severe symptoms or complications of BPH.

Symptoms

- Obstructive symptoms: Slow urinary stream, intermittency, hesitancy, straining to urinate, incomplete emptying, dribbling
- Irritative symptoms: Urgency, frequency, nocturia

Signs

- Digital rectal examination reveals an enlarged prostate (>20 g) with no nodules or indurations; prostate is soft, symmetric, and mobile.

Laboratory Tests

- Increased blood urea nitrogen (BUN) and serum creatinine with long-standing, untreated bladder outlet obstruction, elevated prostate-specific antigen (PSA) level.

Other Diagnostic Tests

- Increased American Urological Association (AUA) Symptom Score, decreased urinary flow rate (<10 mL/s), and increased PVR urine volume.

TREATMENT

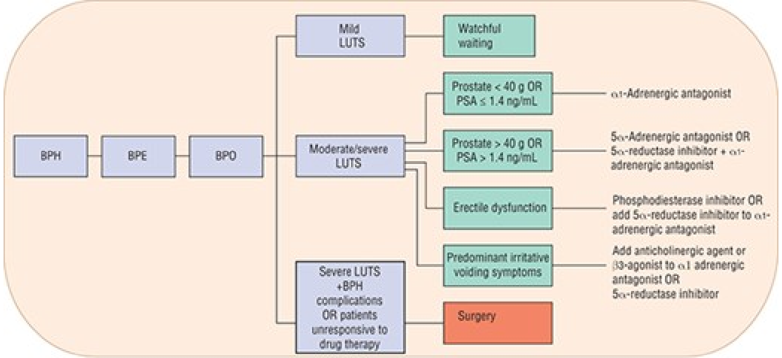
The goals of treatment are to control symptoms, as evidenced by a minimum of a three-point decrease in the AUA symptom index, prevent progression of BPH disease by reducing the risk of developing complications, and delay the need for surgical intervention.

As a disease of symptoms, BPH is treated by relieving bothersome symptoms. However, selection of a single best treatment for a patient must consider the variable costs and adverse effects of treatment options, the inability to predict the course of the disease in an individual patient, and the potential benefit that may occur in a comparatively small number of treated patients.

The 2021 AUA Guidelines on Management of Benign Prostatic Hyperplasia[9] is the principal tool used in the United States and is similar to the 2021 European Guidelines[11] (Fig. 104-2). In a patient with BPH, BPE, or BPO, if symptoms are mild, watchful waiting is recommended. If symptoms are moderate-to-severe with erectile dysfunction, α-adrenergic antagonist, phosphodiesterase inhibitor, or both are recommended. If symptoms are moderate-to-severe with a small prostate and low PSA, α-adrenergic antagonist is recommended. If symptoms are moderate-to-severe with a large prostate and increased PSA, consider 5α-reductase inhibitor plus α-adrenergic antagonist. If symptoms are moderate-to-severe with predominant irritative voiding symptoms, consider α-adrenergic antagonist plus anticholinergic agent, or α-adrenergic antagonist plus mirabegron. If symptoms are severe and the patient has complications of BPH or is not responding to medication therapy, surgical intervention is indicated.[9,11]

FIGURE 104-2

Management algorithm for benign prostatic hyperplasia (BPH).



BPH
BPE
BPO
Mild LUTS
Watchful waiting
Moderate/severe LUTS
Prostate < 40 g OR PSA ≤ 1.4 ng/mL
α1-Adrenergic antagonist
Prostate > 40 g OR PSA > 1.4 ng/mL
5α-Adrenergic antagonist OR 5α-reductase inhibitor + α1-adrenergic antagonist
Erectile dysfunction
Phosphodiesterase inhibitor OR add 5α-reductase inhibitor to α1-adrenergic antagonist
Predominant irritative voiding symptoms
Add anticholinergic agent or β3-agonist to α1 adrenergic antagonist OR 5α-reductase inhibitor
Severe LUTS +BPH complications OR patients unresponsive to drug therapy
Surgery

Specific treatment options include watchful waiting, pharmacologic therapy, and surgical intervention. Although phytotherapy is used by some patients alone or along with conventional medications for BPH, head-to-head comparisons with FDA-approved treatments are lacking; consequently, such herbals cannot be recommended at this time.[9,11]

③ Patients with mild disease are asymptomatic or have mildly bothersome symptoms and have no complications of BPH disease. These patients can be managed with watchful waiting, which entails having the patient return for reassessment at intervals of 6 to 12 months. At each return visit, the patient should complete a standardized, validated survey tool to assess severity of symptoms, and objective signs of disease should be assessed using measurements of urinary flow rate and PVR urine volume. Watchful waiting should be accompanied by patient education about the disease and behavior modification to avoid practices that exacerbate voiding symptoms. Behavior modification includes restricting fluids close to bedtime, minimizing caffeine and alcohol intake, frequent emptying of the bladder during waking hours or before long trips (to avoid overflow incontinence and urgency), smoking cessation, and avoiding drugs that could exacerbate voiding symptoms.[3,8,12,13] At each visit, physicians should assess the patient's risk of developing acute urinary retention by evaluating the patient's prostate size or using PSA as a surrogate marker of prostate enlargement.[14]

④ If symptoms progress to the moderate or severe level, or the patient perceives his symptoms to be bothersome, the patient should be offered specific treatment. In these patients, watchful waiting delays—but does not decrease—the need for prostatectomy. In symptomatic patients, watchful waiting can lead to intractable urinary retention, increased PVR urine volumes, and significant voiding symptoms.[9,11] Recommended treatment options include drug therapy with an α_1-adrenergic antagonist or 5α-reductase inhibitor, a combination of an α_1-adrenergic antagonist and a 5α-reductase inhibitor, a phosphodiesterase inhibitor alone or combined with an α_1-adrenergic antagonist or 5α-reductase inhibitor, or the addition of an anticholinergic agent or a β_3-agonist to an α_1-adrenergic antagonist or 5α-reductase inhibitor particularly if the patient has significant irritative voiding symptoms that are not responsive to an α_1-adrenergic antagonist alone or 5α-reductase inhibitor alone, or surgery.

Patients with serious complications of BPH or patients who do not respond to drug therapy should be offered surgical intervention. Drug therapy is considered an interim measure for such patients because it delays worsening of complications and the need for surgical intervention.[9]

Desired Outcomes

The desired outcomes of treatment include reducing LUTS as evidenced by an improvement of AUA Symptom Score by at least three points, an increase in the peak urinary flow rate, and a normalization of PVR to less than 50 mL. In addition, treatment should prevent the development of disease complications and reduce the need for surgical intervention. Treatment should be well tolerated and be cost-effective.

General Approach to Treatment

In selecting the most appropriate treatment for an individual patient, consideration should be given to the severity and quality of the patient's LUTS, the likelihood of developing complications of BPH (based on size of the prostate gland or the PSA level), the patient's preference for medical versus surgical intervention, the patient's risk for adverse effects of treatment, and the cost of treatment.

Concurrent medical illnesses of the patient should also be considered. For example, if the patient has erectile dysfunction and moderate LUTS, then a phosphodiesterase inhibitor might be preferred over an α_1-adrenergic antagonist. If the patient has overactive bladder syndrome and BPH, irritative voiding symptoms may require the addition of an anticholinergic agent or a β_3-adrenergic agonist. If medical treatment is initiated, the patient's level of renal function should be assessed, as the daily dose of some α-adrenergic antagonists and some anticholinergics require modification to avoid accumulation.

Nonpharmacologic Therapy

BPH is a chronic, nonfatal medical illness. All patients should be encouraged to initiate and maintain a heart-healthy lifestyle, including a low-fat diet, high intake of plenty of fresh fruits and vegetables, regular physical exercise, and no smoking.[15] Patients who have overweight or obesity should be encouraged to lose weight. Those with diabetes mellitus, dyslipidemia, or hypertension should be advised to optimize management of those disorders.[5,8] The patient should avoid excess consumption of caffeine-containing beverages (which may induce diuresis). Patients should void before retiring to bed at night and before long car rides.

Pharmacologic Therapy

Drug therapy for BPH can be categorized into three types: agents that relax prostatic smooth muscle (reducing the dynamic factor), agents that interfere with testosterone's stimulatory effect on prostate gland enlargement (reducing the static factor), and agents that relax bladder detrusor muscle (improving the urine storage capacity of the bladder) (Tables 104-2 and 104-3). Of the agents that relax prostatic smooth muscle, second- and third-generation α_1-adrenergic antagonists have been most widely used. These agents relax the intrinsic urethral sphincter and prostatic smooth muscle, thereby enhancing urinary outflow from the bladder. Phosphodiesterase inhibitors also relax bladder neck and prostatic smooth muscle. α_1-Adrenergic antagonists and phosphodiesterase inhibitors do not reduce prostate size. Of the agents that interfere with testosterone's stimulatory effect on prostate gland size, the only agents approved by the FDA are 5α-reductase inhibitors (eg, finasteride, dutasteride). Other agents that interfere with androgen stimulation of the prostate have not been popular in the United States because of the many adverse effects associated with their use. The luteinizing hormone-releasing hormone superagonists leuprolide and goserelin decrease libido and can cause erectile dysfunction, gynecomastia, and hot flashes. Antiandrogens (eg, bicalutamide, flutamide) produce nausea, diarrhea, gynecomastia, and hepatotoxicity. Finally, antimuscarinic agents and β_3-adrenergic agonists relax the detrusor muscle, which reduces irritable voiding symptoms, improves urine storage capacity of the bladder, and increases the interval between voidings.[9,11–13]

TABLE 104-2

Medical Treatment Options for Benign Prostatic Hyperplasia

Category	Mechanism	Drug (Brand Name)
Reduces dynamic factor	Blocks α_1-adrenergic receptors in prostatic stromal tissue	- Prazosin (Minipress)[a] - Alfuzosin (Uroxatral) - Terazosin (Hytrin) - Doxazosin (Cardura)
	Blocks α_{1A}-adrenergic receptors in prostatic stromal tissue	- Tamsulosin (Flomax) - Silodosin (Rapaflo)
	Inhibits phosphodiesterase type 5 in prostate, urethra, bladder, and pelvic blood vessels	- Tadalafil (Cialis)
Reduces static factor	Blocks 5α-reductase enzyme	- Finasteride (Proscar) - Dutasteride (Avodart)
	Blocks DHT at its intracellular receptor	- Bicalutamide (Casodex)[a] - Flutamide (Eulexin)[a]
	Blocks pituitary release of luteinizing hormone	- Leuprolide (Lupron)[a] - Goserelin (Zoladex)[a]
	Blocks pituitary release of luteinizing hormone and blocks androgen receptor	- Megestrol acetate (Megace)[a]
Relaxes detrusor muscle	Blocks muscarinic receptors in detrusor muscle of bladder	- Tolterodine (Detrol)[a] - Oxybutynin (Ditropan)[a] - Trospium (Sanctura)[a] - Solifenacin (Vesicare)[a] - Darifenacin (Enablex)[a] - Fesoterodine (Toviaz)[a]
	Stimulates β_3-adrenergic receptors in detrusor muscle of bladder	- Mirabegron (Myrbetriq)[a] - Vibegron (Gemtesa)[a]

[a] Not FDA approved for treatment of benign prostatic hyperplasia.

TABLE 104-3

Comparison of α_1-Adrenergic Antagonists, 5α-Reductase Inhibitors, Phosphodiesterase Inhibitors, and Anticholinergic Agents and β_3-Adrenergic Agonists for Benign Prostatic Hyperplasia

	α_1-Adrenergic Antagonists	5α-Reductase Inhibitors
Relaxes prostatic smooth muscle	Yes	No
Decreases prostate size	No	Yes
Halts disease progression	No	Yes
Peak onset	1-6 weeks	3-6 months
Efficacy in relieving BOO	++	++ (for patients with enlarged prostates)
Frequency of dosing	One to two times per day, depending on the agent and dosage formulation	Once per day
Decreases PSA	No	Yes
Sexual dysfunction adverse effects	EJD	Decreased libido, ED, EJD
Cardiovascular adverse effects	Yes	No
	Phosphodiesterase Inhibitors	**Anticholinergic Agents**
Relaxes prostatic smooth muscle	Yes	No
Decreases prostate size	No	No
Halts disease progression	No	No
Peak onset	4 weeks	1-2 weeks
Efficacy in relieving BOO	+	+ (irritative symptoms only)
Frequency of dosing	Once per day	Once per day
Decreases prostate-specific antigen	No	No
Sexual dysfunction adverse effects	No	ED
Cardiovascular adverse effects	Yes (mild hypotension)	Yes (tachycardia)
	β_3-Adrenergic Agonists	
Relaxes prostatic smooth muscle	No	
Decreases prostate size	No	
Halts disease progression	No	

Peak onset	2 weeks, but may take up to 8 weeks	
Efficacy in relieving BOO	+ (irritative symptoms only)	
Frequency of dosing	Once per day	
Decreases prostate-specific antigen	No	
Sexual dysfunction adverse effects	No	
Cardiovascular adverse effects	Yes (hypertension)	

BOO, bladder outlet obstruction; BPH, benign prostatic hyperplasia; ED, erectile dysfunction; EJD, ejaculation disorder; PSA, prostate-specific antigen.

+ Notation is a quantitative assessment.

Selection of a medical treatment for a patient with moderate-to-severe symptoms should be determined on a case-by-case basis after the patient and provider discuss the risks, benefits, and costs of various treatments. With drug therapy for BPH, patients must understand that the benefits continue only as long as the medication is taken.

If possible, drug therapy should be initiated with a single agent, usually an α_1-adrenergic antagonist, which is faster acting and more effective than a 5α-reductase inhibitor. In addition, α_1-adrenergic antagonists are effective in reducing LUTS independent of prostate size and have no effect on PSA. Some are also available as less-expensive generic formulations. A 5α-reductase inhibitor is a good first-choice agent for symptomatic patients with a significantly enlarged prostate (>40 g) and an elevated PSA greater than or equal to 1.4 ng/mL (mcg/L). Such patients are at risk for developing complications of BPH, and typically combination drug therapy with an α_1-adrenergic antagonist and a 5α-reductase inhibitor is prescribed. The pharmacologic rationale for such a combination is that using two drugs with different mechanisms of action can be more effective than either drug alone. Also combination drug therapy quickly relieves symptoms, delays disease progression, and reduces the need for surgical intervention. Since it is more expensive and associated with more adverse effects than single-drug therapy, combination drug therapy should be reserved for those patients who will benefit the most from it.

For patients with both erectile dysfunction and BPH, a phosphodiesterase inhibitor alone or in combination with an α-adrenergic antagonist may be used. However, it should be noted that a phosphodiesterase inhibitor alone will only relieve LUTS, and will not produce a clinically significant increase in urinary flow rate or a decrease in PVR. Therefore, a phosphodiesterase inhibitor is generally considered less effective than an α-adrenergic antagonist.

For patients with a predominance of irritative voiding symptoms, an anticholinergic agent could be added to an existing drug regimen for BPH. To reduce the risk of developing systemic anticholinergic adverse effects, a uroselective anticholinergic agent may be prescribed. To avoid the risk of developing acute urinary retention, an anticholinergic agent should be used cautiously when the patient’s PVR is greater than 250 to 300 mL. Mirabegron and vibegron are more expensive than many anticholinergic agents. Therefore, they should be reserved as an add-on treatment for patients with irritative voiding symptoms who cannot tolerate anticholinergic adverse effects.

α_1-Adrenergic Antagonists

Three generations of α-adrenergic antagonists have been used to treat BPH. They all relax smooth muscle in the prostate and bladder neck. Because antagonism of presynaptic α_2-adrenergic receptors produces tachycardia and arrhythmias, first-generation α-adrenergic agents, such as phenoxybenzamine, have been replaced by the second-generation postsynaptic α_1-adrenergic antagonists and third-generation uroselective postsynaptic α_{1A}-adrenergic antagonists.

⑤ The second- and third-generation α_1-adrenergic antagonists are considered equally effective for treatment of BPH.[9,16] These agents generally improve the AUA Symptom Score by 30% to 40%, decreasing the AUA Symptom Index by three to six points, within 1 to 6 weeks, depending on the need for dose titration; increase urinary flow rate by 2 to 3 mL/s in 60% to 70% of treated patients; and reduce PVR urine volume.[3,12,16] With continued use, durable clinical benefit has been demonstrated for years.[9] Their effectiveness in reducing BPH symptoms and the severity of adverse effects are dose-dependent.[9] They have no effect on prostate volume. α_1-Adrenergic antagonists do not reduce PSA levels, preserving the utility of this prostate cancer marker in this high-risk population.[9]

Older, immediate-release, second-generation α_1-adrenergic antagonists, and tamsulosin are available as inexpensive generic formulations, which may be desirable in selected patients.

Second-Generation α_1-Adrenergic Antagonists

Second-generation agents include prazosin, terazosin, doxazosin, and alfuzosin. These are all nonselective α_1-adrenergic antagonists. At the usual doses used to treat BPH, immediate-release formulations of prazosin, terazosin, and doxazosin antagonize peripheral vascular α_1-adrenergic receptors. As a result, first-dose syncope, orthostatic hypotension, and dizziness are characteristic adverse effects. In older adults, such adverse effects could lead to falls and bone fractures.[3,15,17] To improve tolerance to these adverse effects, therapy should start with a low dose of 1 mg daily and then should be slowly titrated up to a full therapeutic dose over several weeks. Additive blood-pressure-lowering effects commonly occur when these agents are used with antihypertensive agents, which limit the use of these agents for some patients. These agents differ in terms of duration of action and dosage formulation. Prazosin requires twice- to thrice-daily dosing and has significant cardiovascular adverse effects. For these reasons, it is not recommended in the current AUA guidelines for treatment of BPH.[9] Extended-release dosage formulations of doxazosin and alfuzosin offer the convenience of once-daily dosing, treatment initiation with a full therapeutic dose, and decreased dose-related hypotension because they produce lower peak serum concentrations than immediate-release products.

An α_1-adrenergic antagonist is not preferred as single-drug therapy for treatment of both BPH and hypertension in a patient. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) of 24,000 patients with hypertension, doxazosin produced more congestive heart failure than amlodipine, lisinopril, or chlorthalidone.[18] Thus, both the AUA and the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure[9,19] recommend that patients with BPH and hypertension be treated with separate and appropriate drug treatment for each medical condition.

When using immediate-release formulations of the second-generation α_1-adrenergic antagonists terazosin and doxazosin, slow titration up to a therapeutic maintenance dose is necessary to minimize orthostatic hypotension and first-dose syncope. Conservatively, dosages should be increased in an orderly stepwise process, at 2- to 7-day intervals, depending on the patient's response to the medication. A faster titration schedule can be used as long as the patient does not develop orthostatic hypotension or dizziness. Two sample titration schedules for terazosin are as follows:

Schedule 1: Slow titration

- Days 4 to 14: 2 mg at bedtime
- Weeks 2 to 6: 5 mg at bedtime
- Weeks 7 and on: 10 mg at bedtime

Schedule 2: Quicker titration

- Days 1 to 3: 1 mg at bedtime
- Days 4 to 14: 2 mg at bedtime
- Weeks 2 to 3: 5 mg at bedtime
- Weeks 4 and on: 10 mg at bedtime

In addition, patients should take their dose at bedtime so that they can sleep through hypotensive side effects that are most likely to occur when peak blood levels are achieved. Patients should continue taking the drug as long as they continue to respond to it. Durable responses for 10 years have been reported for doxazosin.[9]

Alfuzosin is considered functionally and clinically uroselective in that usual doses used to treat BPH are less likely than other second-generation agents to cause cardiovascular adverse effects in animal or human models.[9] This clinical effect has been observed more often with the once-daily, extended-release formulation of alfuzosin, which is the only commercially available formulation in the United States. Its clinical uroselectivity has been postulated to be due to higher concentrations of alfuzosin achieved in the prostate versus serum after usual doses,[20,21] absence of high peak serum levels with the extended-release formulation, and the fixed dosing schedule of the extended-release formulation. Extended-release alfuzosin dosing is FDA approved for 10 mg daily, with no dose titration increase. This formulation is particularly convenient for patients who have difficulty remembering varying doses needed for up-titration dosing schedules.

Third-Generation α_1-Adrenergic Antagonists

Three subtypes of α_1-adrenergic receptors exist: (a) α_{1A}, which comprise 70% to 75% of the α-adrenergic receptors in the prostate, bladder neck, prostatic urethra, seminal vesicles, spermatic duct, and vas deferens (when stimulated, smooth muscle contraction and the emission phase of ejaculation occurs)[20,21]; (b) α_{1B}, which cause peripheral arterial smooth muscle contraction when stimulated; and (c) α_{1D}, which are found in the detrusor muscle of the bladder, prostate, urethra, and brain, but their function remains to be defined.[22]

Third-generation α_1-adrenergic antagonists preferentially inhibit α_{1A}-adrenergic receptors. Tamsulosin and silodosin are the only third-generation α_{1A}-adrenergic antagonists available in the United States. Blockade of these receptors relaxes smooth muscle of the prostate and bladder neck and improves bladder emptying in patients with BPH, but blockade is likely to cause ejaculatory disorders. In addition, both of these agents have low affinity for vascular α_{1B}-adrenergic receptors, which explains why hypotension is not as frequent with usual daily doses as compared with second-generation agents.[9]

Silodosin has 50-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1D}-adrenergic receptor and has 100-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1B}-adrenergic receptor.[9,23] Silodosin demonstrates greater pharmacologic uroselectivity than tamsulosin, which has a 10-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1D}-adrenergic receptor and has 2.5-fold greater selectivity for the α_{1A}-adrenergic receptor than the α_{1B}-adrenergic receptor.[24] These pharmacologic differences are not associated with a significant difference in efficacy, but there is a higher incidence of ejaculatory disorders as an adverse effect in silodosin-treated patients as opposed to tamsulosin-treated patients.[23–25]

The uroselectivity of α_{1A}-adrenergic receptors has multiple implications. Dose titration is minimal; therefore, patients can start treatment with a therapeutic dose of tamsulosin 0.4 mg daily or silodosin 8 mg daily. Patients can be instructed to take the dose anytime during the day. It should be noted that the product labeling of tamsulosin and silodosin state that they should be taken 30 minutes after the same meal every day. Food decreases their oral bioavailability, reduces the peak serum concentration of the drug, and lowers the risk of hypotensive adverse effects. The onset of peak action is quick, in the range of 1 week. Increasing the daily dose of tamsulosin to 0.8 mg daily produces inconsistent improvements in effectiveness but does increase adverse effects.[26] These agents are well tolerated in patients with well-controlled hypertension; and the addition of tamsulosin to furosemide, enalapril, nifedipine, and atenolol does not result in hypotension.[27]

As compared with tamsulosin, silodosin requires dosage reduction in patients with a creatinine clearance of 30 to 50 mL/min (0.5-0.83 mL/s), is contraindicated in patients with severe hepatic insufficiency or a creatinine clearance less than 30 mL/min (0.5 mL/s), and has the potential to produce more adverse effects because of elevated plasma concentrations if used concurrently with potent CYP 3A4 inhibitors (eg, clarithromycin, itraconazole, ketoconazole, ritonavir) or P-glycoprotein inhibitors (eg, cyclosporine). Silodosin also causes more ejaculatory dysfunction than tamsulosin.[25,28] Finally, silodosin is commercially available from only one source, whereas tamsulosin is available as a generic formulation.

The usual doses of α_1-adrenergic antagonists are summarized in Table 104-4.

TABLE 104-4

Dosing of Drugs Used in Treatment of Benign Prostatic Hyperplasia

Drug	Brand Name	Initial Dose	Usual Dose	Special Population Dose
α-Adrenergic Antagonists				
Prazosin	Minipress	0.5 mg twice a day orally	1-5 mg twice a day orally	To uptitrate the dose, double the dose every 2 weeks.
Terazosin	Hytrin	1 mg at bedtime orally	10-20 mg daily orally	Take extra care if the patient is taking other drugs that lower blood pressure. No dosage adjustment is required for patients with renal or hepatic impairment.
Doxazosin	Cardura	1 mg daily orally	8 mg daily orally	When switching from the immediate- to the extended-release formulation, start with 4 mg of the extended-release formulation no matter what maintenance dose of immediate-release doxazosin the patient is taking. No dosage adjustment is required for patients with renal or hepatic impairment.
	Cardura XL	4 mg daily orally	4-8 mg daily	
Alfuzosin	Uroxatral	10 mg daily orally	10 mg daily orally (no dose titration)	This is an extended-release formulation, and it should not be chewed or crushed. The drug should be taken after meals and used cautiously in patients with creatinine clearance less than 30 mL/min (0.5 mL/s). No dosage adjustment is required for patients with mild hepatic impairment. It is contraindicated in patients with moderate-to-severe hepatic impairment.
Tamsulosin	Flomax	0.4 mg daily orally	0.4-0.8 mg daily orally	This is an extended-release formulation, and it should not be chewed or crushed. The drug should be taken after meals. No dosage adjustment is needed in patients with renal or liver impairment.
Silodosin	Rapaflo	8 mg daily orally	8 mg daily orally (no dose titration)	This drug is contraindicated when creatinine clearance is less than 30 mL/min (0.5 mL/s). If creatinine clearance is 30-50 mL/min (0.5-0.83 mL/s), use 4 mg daily orally, preferably after the same meal each day. No dosage adjustment is required for patients with mild-to-moderate hepatic impairment. Should not be given to patients on potent CYP 3A4 inhibitors or with severe hepatic impairment.
5α-Reductase Inhibitors				
Finasteride	Proscar	5 mg daily orally	5 mg daily orally	No dosage adjustment in patients with renal impairment. Use cautiously in patients with hepatic impairment.
Dutasteride	Avodart	0.5 mg daily orally	0.5 mg daily orally	No dosage adjustment in patients with renal impairment. Use cautiously in patients with hepatic impairment.
Dutasteride + tamsulosin	Jalyn	1 tablet (equivalent to 0.5-mg dutasteride	1 tablet daily orally	No dosage adjustment needed in patients with renal or moderate hepatic impairment.

		+ 0.4-mg tamsulosin) daily orally		
Phosphodiesterase Inhibitor				
Tadalafil	Cialis	5 mg daily orally	5 mg daily orally	If creatinine clearance is 30-50 mL/min (0.5-0.83 mL/s), use 2.5 mg daily orally. Do not use if creatinine clearance is less than 30 mL/min (0.5 mL/s). Use cautiously in patients with mild-moderate hepatic impairment. Avoid in patients with severe hepatic impairment.
Anticholinergic Agents				
Darifenacin	Enablex	7.5 mg daily orally	7.5-15 mg daily orally	This is an extended-release formulation and it should not be chewed or crushed. To up-titrate the dose, double the dose after 2 weeks. If the patient is taking a potent CYP3A4 inhibitor (eg, ketoconazole, itraconazole, ritonavir, nelfinavir, and clarithromycin), do not exceed 7.5 mg daily orally. No dosage adjustment is needed for patients with renal impairment. Use a maximum dose of 7.5 mg daily for patients with moderate hepatic impairment. Do not use in patients with severe hepatic impairment.
Fesoterodine	Toviaz	4 mg daily orally	4-8 mg daily orally	This is an extended-release formulation, and it should not be chewed or crushed. If the patient is taking a potent CYP3A4 inhibitor (eg, ketoconazole, itraconazole, ritonavir, nelfinavir, and clarithromycin), do not exceed 4 mg daily orally. If the creatinine clearance is less than 30 mL/min (0.5 mL/s), do not exceed 4 mg daily orally. Use is not recommended in patients with severe hepatic impairment.
Oxybutynin	Ditropan	5 mg two to three times a day orally	5-10 mg two to three times a day orally	Increase daily dose at 5-mg increments at weekly intervals. No specific dosing modifications available for patients with renal or hepatic impairment; use cautiously in these patients.
	Ditropan XL	5 mg daily orally	5-30 mg daily orally	This is an extended-release formulation, and it should not be crushed or chewed. Increase daily dose at 5-mg increments at weekly intervals. No specific dosing modifications available for patients with renal impairment; use cautiously in these patients.
	Oxytrol TDS	1 patch (3.9-mg oxybutynin) twice weekly	1 patch (3.9 mg) twice weekly	This is a transdermal patch. Apply to abdomen, hip, or buttock. Rotate application site. Do not expose patch to sunlight. No specific dosing modifications available for patients with renal or hepatic impairment; however, use cautiously in these patients.
	Gelnique 10% gel	1-g gel (100-mg oxybutynin) daily	1-g gel (100-mg oxybutynin) daily	This is available as premeasured dose packets. Apply to abdomen, thighs, upper arms, or shoulders. Wash hands after application. Do not bathe, shower, or swim for 1 hour after application. Cover application site with clothing until medication dries on skin. Rotate application site daily. No specific dosing modifications available for patients with renal or hepatic impairment; use cautiously in these patients.
Solifenacin	VESIcare	5 mg daily orally	5-10 mg daily orally	If the creatinine clearance is less than 30 mL/min (0.5 mL/s) or the patient has moderate hepatic impairment, do not exceed 5 mg daily orally. Do not use if the patient has severe hepatic impairment. If the patient is taking a potent CYP3A4 inhibitor (eg, ketoconazole, itraconazole, ritonavir, nelfinavir, and clarithromycin), do not exceed 5 mg daily orally

Tolterodine	Detrol	2 mg twice daily orally	1-2 mg twice daily orally	If the patient has significant renal impairment or severe hepatic impairment, limit dose to 1 mg twice a day.
	Detrol LA	4 mg daily orally	2-4 mg daily orally	This is an extended-release formulation, and it should not be chewed or crushed. If the creatinine clearance is 10-30 mL/min (0.17-0.5 mL/s) or the patient has mild-moderate hepatic impairment, do not exceed 2 mg daily orally. If the creatinine clearance is less than 10 mL/min (0.17 mL/s), do not use Detrol LA. If the patient has severe hepatic impairment, use of the extended-release formulation is not recommended.
Trospium	Sanctura	20 mg twice daily orally	20 mg twice daily orally	Avoid alcohol ingestion for 2 hours after a dose. Use cautiously in patients with moderate-severe hepatic impairment. In patients older than 75 years, use the immediate-release formulation and start with 20 mg daily orally. If the creatinine clearance is less than 30 mL/min (0.5 mL/s), use 20-mg immediate-release formulation
	Sanctura XR	60 mg daily orally	60 mg daily orally	This is an extended-release formulation, and it should not be chewed or crushed. This is not recommended in patients with creatinine clearance less than 30 mL/min (0.5 mL/s). This should be used cautiously in patients with severe hepatic impairment.
β_3-Adrenergic Agonist				
Mirabegron	Myrbetriq	25 mg daily orally	25-50 mg daily orally	This is an extended-release formulation. Do not chew, crush, or divide tablet. In patients with a creatinine clearance of 15-29 mL/min (0.25-0.48 mL/s) or those with moderate hepatic impairment, the maximum daily dose should be 25 mg daily. This drug is not recommended in patients with creatinine clearance less than 15 mL/min (0.25 mL/s) or those with severe hepatic impairment.
Vibegron	Gemtesa	75 mg daily orally	75 mg daily orally (no dose titration)	This tablet may be crushed and administered in applesauce or put into a glass of water for ease of administration. No dosage adjustment for patients with a creatinine clearance of 15 mL/min (0.25 mL/s) or more. Do not use in patients with creatinine clearance less than 15 mL/min (0.25 mL/s). No dosage adjustment for patients with mild-to-moderate hepatic impairment. Do not use in patients with severe hepatic impairment.

Adverse Effects

Approximately 10% to 12% of patients discontinue taking second-generation α_1-adrenergic antagonists because of adverse effects, especially those that affect the cardiovascular system (eg, syncope, dizziness, hypotension).[9,11] Patients who tolerate hypotension poorly should avoid immediate-release formulations of second-generation α_1-adrenergic antagonists. This includes patients with poorly controlled angina, serious cardiac arrhythmias, patients with reduced circulating volume, patients with untreated hypertension, and patients taking multiple antihypertensives.[15] Alfuzosin, extended-release doxazosin, or a third-generation α_1-adrenergic antagonist is preferred in these patients.

Tiredness and asthenia, anejaculation and retrograde ejaculation, flu-like symptoms, and nasal congestion are the most common dose-related adverse effects of tamsulosin and silodosin. These adverse effects are extensions of their α_{1A}-adrenergic antagonist activity and are dose-related, but with proper education patients likely will not discontinue treatment. However, if the patient is sexually active and ejaculatory dysfunction is problematic, switching the patient from a third-generation to a second-generation α_1-adrenergic antagonist has been effective.[27,29–32]

Tamsulosin use has been associated with dementia based on analysis of a cohort of patients in the Medicare database from 2006 to 2012.[33] It was hypothesized that dementia was due to blockade of α_{1A}-adrenergic receptors in the brain, as this association was not found with second-generation α_1-adrenergic antagonists.[33] However, conflicting data showing no such association have also been reported.[34]

Floppy iris syndrome has been associated with doxazosin, silodosin, and tamsulosin use, although the number of reported cases is highest with tamsulosin.[35] The mechanism for this adverse reaction is related to blockade of α_{1A}-adrenergic receptors in iris dilator muscles. As a result, during cataract surgery, pupillary constriction occurs despite the use of mydriatic agents and the iris billows out (floppy iris), both of which complicate the procedure or can increase the likelihood of postoperative complications, including posterior capsular rupture, retinal detachment, residual retained lens material, or endophthalmitis. Permanent loss of vision can result.[35,36]

Patients who are taking α_1-adrenergic antagonists and who plan to undergo cataract surgery should inform their ophthalmologist that they are taking this medication so that appropriate measures can be taken during eye surgery, for example, use of iris retractors, pupillary expansion rings, or potent mydriatic agents.[36] No benefit has been demonstrated with holding the α_1-adrenergic antagonist preoperatively.

For patients who are scheduled to have cataract surgery, and who have not yet started an α_1-adrenergic antagonist, they should be advised to delay the start of the α_1-adrenergic antagonist until surgery has been completed.[3,9]

Patients with severe sulfa allergy should avoid tamsulosin.

Drug Interactions

Caution is needed when CYP 3A4 inhibitors—for example, cimetidine and diltiazem—are used with α_1-adrenergic antagonists because a drug-drug interaction could lead to decreased metabolism of the latter agents. In contrast, concurrent use of potent CYP 3A4 stimulators such as carbamazepine and phenytoin may increase hepatic catabolism of α_1-adrenergic antagonists.

Phosphodiesterase inhibitors (eg, sildenafil, vardenafil, tadalafil) may produce hypotension if used in large doses along with α_1-adrenergic antagonists. The mechanisms for this interaction are related to the intrinsic vasodilatory effects of phosphodiesterase inhibitors and the higher susceptibility of elderly patients to venous pooling because of autonomic incompetence.[37] The prevalence of hypotension depends on the specific phosphodiesterase inhibitor and α_1-adrenergic antagonist agent, specifically the combination of tadalafil and a third-generation α_{1A}-adrenergic antagonist is least likely to produce a clinically significant drug interaction, as compared with other combinations.[38] Therefore, a patient's blood pressure should be stabilized on the α_1-adrenergic antagonist before starting a phosphodiesterase inhibitor. In addition, patients who are taking phosphodiesterase inhibitors with α_1-adrenergic antagonists should have their blood pressure monitored closely when initiating combined drug use.

5α-Reductase Inhibitors

⑥ Finasteride competitively inhibits type II 5α-reductase, the predominant isoform of the enzyme in the prostate, which suppresses intraprostatic DHT by 80% to 90%, and decreases serum DHT levels by 70%.[9] Dutasteride is a nonselective inhibitor of type I and II 5α-reductase. It more quickly and completely suppresses intraprostatic DHT production and decreases serum DHT levels by 90%.[39] However, direct comparison clinical trials show no advantages of these pharmacodynamic differences between these two agents.[39] 5α-Reductase inhibitors are indicated for management of moderate-to-severe BPH disease for patients with enlarged prostate glands of at least 40 g or a PSA greater than 1.4 ng/dL (mcg/L).[9,11,40,41] For such patients, 5α-reductase inhibitors may slow disease progression and decrease the risk of disease complications, thereby decreasing the ultimate need for surgical intervention. When taken continuously for 4 or 6 years, dutasteride or finasteride, respectively, has been shown to decrease the risk of acute urinary retention and prostatectomy.[3,42,43] For patients with severe disease, these agents generally should be used with a 6-month short course of an α_1-adrenergic antagonist; the latter will provide fast symptom relief until the 5α-reductase inhibitor starts to work. 5α-Reductase inhibitors may be preferred for patients with BPH and an enlarged prostate gland who have uncontrolled arrhythmias, have poorly controlled angina, are taking multiple antihypertensive agents, or are unable to tolerate hypotensive adverse effects of α_1-adrenergic antagonists.[13]

5α-Reductase inhibitors also reduce or stop prostate-related bleeding by inhibiting prostatic vascular endothelial growth factor. Thus, the prevalence of gross hematuria in patients with BPH may be reduced with treatment of 5α-reductase inhibitors.[9]

5α-Reductase inhibitors reduce prostate size by 25%, increase peak urinary flow rate by 1.6 to 2.0 mL/s, improve voiding symptoms in approximately 30% of treated patients, and produce few serious adverse effects.[9,11,12]

Compared with α_1-adrenergic antagonists, 5α-reductase inhibitors have several disadvantages. 5α-Reductase inhibitors have a delayed peak onset of clinical effect, which is undesirable for patients with bothersome symptoms. Long-term treatment is needed; an adequate minimum period for a clinical trial is 6 to 12 months. In addition, patients experience less objective improvement of the AUA Symptom Score and urinary flow rate with 5α-reductase inhibitors than with α_1-adrenergic antagonists.[9] 5α-Reductase inhibitors cause more sexual dysfunction than α_1-adrenergic receptor antagonists; therefore, physicians consider 5α-reductase inhibitors to be the second-line agents for treatment of BPH in sexually active males (Tables 104-3 and 104-5).[9,44]

TABLE 104-5

Monitoring of Drugs Used in Treatment of Benign Prostatic Hyperplasia

Drug	Adverse Reaction	Monitoring Parameter	Comment
α_1-Adrenergic antagonists	• Syncope • Lightheadedness • Orthostatic hypotension • Tachycardia • Nasal congestion • Ejaculatory dysfunction • Priapism • Floppy iris syndrome	• Blood pressure • Heart rate	If prescribing an immediate-release formulation, start the patient on the lowest possible dose and instruct the patient to take the first dose at bedtime. Slowly uptitrate the dose over several weeks. Stabilize the patient's blood pressure on the α_1-adrenergic antagonist before adding any other hypotensive agent. If the patient needs cataract surgery, instruct the patient to inform the ophthalmologist so that appropriate measures can be taken during the procedure to prevent intraoperative complications. If the patient has a painful erection lasting longer than 4 hours, the patient should seek immediate medical attention.
5α-Reductase inhibitors	• ED • Decreased libido • Ejaculatory dysfunction • Gynecomastia	• PSA	The patient's PSA level should decrease by 50% if he is adherent to therapy.
Phosphodiesterase inhibitor	• Headache • Dizziness • Nasal congestion • Dyspepsia • Back pain • Myalgia • Hearing loss • Vision loss	• Blood pressure • Pulse • Hearing loss • Changes in vision	If the patient experiences hearing or vision loss, discontinue tadalafil.
Anticholinergic	• Dry mouth	• Mental	Adverse effects are dose-related and generally reversible. Patients with signs of severe

agents	Constipation Headache Tachycardia Blurry vision Acute urinary retention Drowsiness Confusion Angioedema Anaphylaxis ED	status Bowel habits Ability to urinate	allergic reaction need immediate medical attention.
β_3-Adrenergic agonist	Hypertension Tachycardia Dry mouth Nausea Constipation Diarrhea Headache Nasopharyngitis Impaired cognition	Blood pressure Bowel habits	Adverse effects are dose-related and generally reversible.

ED, erectile dysfunction; PSA, prostate-specific antigen.

Prostate Cancer and 5α-Reductase Inhibitors

In the Prostate Cancer Prevention Trial, patients with BPH who had large prostate glands and a PSA level less than 3 ng/mL (mcg/L) were prescribed finasteride 5 mg daily for up to 7 years. Finasteride reduced the 7-year prevalence of prostate cancer by 25%.[45] However, finasteride was associated with a 27% increase in the number of patients who developed high-grade prostate cancer, which usually is invasive. Although originally thought to be a disadvantage of finasteride use, it is now thought that the higher incidence of prostate cancer was due to biopsy sampling bias. That is, since finasteride reduces the size of the prostate gland, this results in increased sensitivity of sampling biopsies to detect prostate cancer.[46]

Another clinical trial produced similar results. The Reduction by Dutasteride in Prostate Cancer Events (REDUCE) study compared the effect of 4 years of continuous use of dutasteride versus placebo on reducing the incidence of prostate cancer in more than 6,700 men at high risk for developing prostate cancer. At the end of the study, dutasteride-treated patients had a 22.8% decreased relative risk of prostate cancer. Of the patients with biopsy-positive prostate cancer, a similar number of patients in each treatment group developed high-grade tumors (Gleason grade 7-10) with no statistical difference between the groups.[47]

Thus, when finasteride is administered long-term to patients with BPH, it could be useful as chemoprophylaxis in patients with a family history of prostate cancer or in men of African descent who have an increased risk of developing prostate cancer. Although a cause-effect relationship has not been established, the possibility of developing a high-grade prostate cancer should be discussed with the patient before initiating a 5α-reductase inhibitor for prevention of prostate cancer.[45,48]

Dosing

Table 104-6 compares the pharmacokinetic properties of finasteride and dutasteride. They both exhibit good oral bioavailability, are extensively metabolized by the liver, and are highly protein bound. The principal difference is in the drugs' half-life: 5 to 6 hours for finasteride and 5 weeks for dutasteride. Although dutasteride's long half-life may allow for intermittent dosing as opposed to daily dosing, insufficient clinical data are available to recommend such a dosing schedule.

TABLE 104-6

Comparison of Pharmacokinetic Properties of Finasteride and Dutasteride

	Finasteride	Dutasteride
Daily oral dose (mg)	5	0.5
Dosage formulation	Tablet	Capsule
Effect of food on absorption	No effect	No effect
% Oral bioavailability	63	60
Time to peak absorption (hours)	1-2	2-3
Elimination half-life	5-6 hours	5 weeks
% Protein binding	90	99

Maximal reductions in prostate volume or symptom improvement may not be evident for 12 months, but noticeable changes from baseline should occur after 6 months of continuous treatment.

Patients must continue to take 5α-reductase inhibitors as long as they respond. Durable responses to finasteride and dutasteride have been reported with continued treatment for 6 years[43] and 4 years,[40] respectively. Upon discontinuation of the drug, prostate size and voiding symptoms generally return to baseline.

No clinically relevant drug interactions have been reported with 5α-reductase inhibitors.

Adverse Effects

5α-Reductase inhibitors can produce sexual dysfunction, and this has led to discontinuation of therapy in up to 12% of treated patients in one-pooled analysis.[40] Decreased libido has been reported in 2% to 10% of treated patients.[44] Erectile dysfunction has been reported in 3% to 16% of patients.[40,44] This could be secondary to ejaculation disorders or a drug-induced decrease in DHT and subsequent inhibition of nitric oxide synthase (which is needed to produce nitric oxide, a vasodilatory substance) in cavernosal tissue.[32] Although sexual dysfunction often improves with time as the patient continues to take the medication, decreased libido and erectile dysfunction may persist after discontinuation of the 5α-reductase inhibitors.[49–51] The role of 5α-reductase inhibitors in causing erectile dysfunction is not clear, as older adult men with BPH commonly develop erectile dysfunction as they age or have concurrent medical illnesses or concomitant drug therapies that may predispose to the development of sexual dysfunction.

Ejaculation disorders (dry sex or delayed ejaculation) have been reported in 3% to 8% of treated patients.[49,50] These disorders, which are possible results of decreased prostatic secretion, are reversible with drug discontinuation. In one analysis, dutasteride was associated with a higher frequency of sexual dysfunction than finasteride.[52]

Other minor adverse effects include nausea, abdominal pain, asthenia, dizziness, flatulence, headache, rash, muscle weakness, and gynecomastia.[9,53] Mental depression and an increased risk of self-harm have been associated with the first 1.5 years of treatment with a 5α-reductase inhibitor; however, a cause-effect relationship has not been established.[54,55]

5α-Reductase inhibitors are in FDA pregnancy category X, which means that they are contraindicated in pregnant females. Exposure of the male fetus to finasteride may produce pseudohermaphroditic offspring with ambiguous genitalia, similar to those of patients with a rare genetic deficiency of type II 5α-reductase. Because of this teratogenic effect, women who are pregnant or seeking to become pregnant should not handle 5α-reductase inhibitor tablets and should not have contact with semen from men being treated with 5α-reductase inhibitors. Women health professionals of childbearing age should handle this product with protective gloves if they might be pregnant.

Effects of 5α-Reductase Inhibitors on PSA

DHT stimulates prostate epithelial cells to produce PSA. Since 5α-reductase inhibitors inhibit intracellular conversion of testosterone to DHT, these medications can decrease PSA production.

Usual doses of 5α-reductase inhibitors produce a median reduction of serum PSA levels of 50% at months 6 to 12 after the start of treatment. To interpret a PSA level in a patient being treated with a 5α-reductase inhibitor, it is generally recommended that the actual measured level be doubled to get an estimate of the true level.[9] This formula applies particularly when the baseline PSA value is 4 ng/mL (mcg/L) or more.[56] PSA levels must be measured and a digital rectal examination should be performed before treatment begins. After 6 months of therapy, the patient should have a repeat PSA. This PSA level can be used as the new baseline for the patient. Alternatively, when compared to the pretreatment PSA, if the during-treatment level does not decline by 50% but the patient has been adherent to the 5α-reductase inhibitor regimen, he should be evaluated for prostate cancer. Annually thereafter, the patient should have a PSA assay and digital rectal examination if the patient has a 10-year life expectancy. Patients with an increase in PSA level of 0.3 ng/mL (mcg/L) or more above the baseline nadir level should be evaluated for prostate cancer[9] or noncompliance to the prescribed regimen.

Phosphodiesterase Type 5 Inhibitors

⑦ Several observations led to the use of phosphodiesterase type 5 inhibitors for management of BPH. (1) BPH and erectile dysfunction are often present concurrently in the same patient. (2) The pathophysiology of BPH and erectile dysfunction may be common in so far as both disorders may be associated with increased smooth muscle contraction and pelvic atherosclerosis. (3) Improvement of BPH symptoms has been reported to ameliorate erectile dysfunction; and vice versa. (4) Using a phosphodiesterase type 5 inhibitor with a 5α-reductase inhibitor is reasonable as the former will effectively treat erectile dysfunction, a side effect of the latter.[9,57]

Phosphodiesterase type 5 inhibitors relax smooth muscle in the prostate, urethra, bladder neck, and pelvic blood vessels, probably by increasing cGMP. By so doing, phosphodiesterase type 5 inhibitors interrupt the Rho-protein kinase pathway (which regulates smooth muscle contraction mediated by endothelin and α-adrenergic stimulation), improve perfusion of pelvic organs and oxygenation to tissue[57], and possibly decrease inflammation.[58]

In multiple clinical trials of patients with moderate LUTS, tadalafil caused a mean two-point improvement in both obstructive and irritative voiding symptoms using the AUA Symptom Index Score or International Prostate Symptom Score (IPSS), with the level of improvement similar to that observed with α_1-adrenergic antagonists.[58,59] However, no or minimal increase in urinary flow rate or reduction in PVR occurred with tadalafil alone. Tadalafil 2.5 mg was inferior to 5 mg, and doses of 10 or 20 mg were not superior to 5 mg.[60] This is the basis of the current product labeling dose of tadalafil 5 mg daily for BPH. The onset of clinical symptom improvement is within 4 weeks.[60] Tadalafil is more effective for BPH in younger men with symptomatic LUTS. It may be that these patients are more likely to be sexually active. Therefore, when treating both BPH and erectile dysfunction, tadalafil improves a patient's perception of the medication's effectiveness.[37]

A few other BPH studies have employed sildenafil 50 or 100 mg daily, vardenafil 10 mg twice a day, or tadalafil 10 or 20 mg daily.[60] Based on a recent meta-analysis, all phosphodiesterase type 5 inhibitors produce comparable improvements of LUTS, but tadalafil is the only one that has been FDA approved for the treatment of BPH.[60] Tadalafil has the longest plasma half-life and longest duration of action among the phosphodiesterase type 5 inhibitors. This pharmacokinetic characteristic is conducive for the treatment of BPH, which is a chronic illness.

Dosing Recommendations

The recommended tadalafil dose is 5 mg daily. Based on the limited clinical benefit, cost, and potential adverse effects of tadalafil, its use should be reserved for patients with both BPH and erectile dysfunction. Patients with known cardiovascular disease should be assessed and stratified according to the Princeton Consensus Panel guidelines[61] to identify those patients who can safely use tadalafil. If used in combination with an α-adrenergic antagonist, precautions should be taken to minimize hypotension, specifically, the patient's blood pressure should be stabilized on the α_1-adrenergic antagonist before adding tadalafil.[37] If used in combination with a 5α-reductase inhibitor, tadalafil may be used instead of an α-adrenergic antagonist, and the combination may be associated with less sexual dysfunction, particularly in younger, sexually active patients.

Adverse Effects

The most common adverse effects with tadalafil are headache, flushing, gastroesophageal reflux, sinusitis, visual disturbances, and back pain, which are generally mild and reversible and do not require discontinuation of therapy. Headache and dizziness are related to the vasodilatory effect of tadalfil. If tadalafil is an add-on to an existing α_1-adrenergic antagonist and the patient is at risk of hypotensive adverse effects, it is recommended that: (a) the patient's blood pressure be stabilized on the α_1-adrenergic antagonist before tadalafil is started; (b) once tadalafil is started, separate its administration from the α_1-adrenergic antagonist by 4 hours; and (c) preferentially prescribe tamsulosin, silodosin, or alfuzosin as opposed to other α_1-adrenergic antagonists. Back pain has been linked to tadalafil's inhibition of phosphodiesterase type 11. This usually responds to acetaminophen or a nonsteroidal anti-inflammatory agent.

Drug Interactions

Nitrates by any route of administration are contraindicated in patients taking tadalafil.

Anticholinergic Agents

Five types of muscarinic receptors have been identified: (1) M_1 that concentrate in the brain, stomach, and salivary glands; (2) M_2 that comprise 71% to 75% of the muscarinic receptors in the urinary bladder and also are found in the gastrointestinal tract and the atrioventricular node of the heart; (3) M_3 comprise 25% to 29% of the muscarinic receptors in the urinary bladder, and are also distributed in salivary glands, gastrointestinal tract, airways, and eyes; (4) M_4 that are found in the urinary bladder and central nervous system; and (5) M_5 that are found in the brain and eyes. Although M_2 receptors predominate in the urinary bladder, increased M_3 receptor stimulation has been linked with irritative bladder symptoms and overactive bladder syndrome. For this reason, M_3 selective anticholinergic agents eg, (eg, solifenacin and tolterodine) are considered uroselective. However, since M_3 receptors are widely distributed in other organ systems, this explains why darifenacin, a uroselective anticholinergic agent, causes dry mouth, constipation, and mydriasis.[8,9]

⑧ Treatment with an α_1-adrenergic antagonist, 5α-reductase inhibitor, or surgery may improve urinary flow rate and bladder emptying; however, the patient may still complain of irritative voiding symptoms, which mimic those of overactive bladder syndrome. A variety of anticholinergic agents have been added to an α-adrenergic antagonist regimen to relieve these symptoms.[9,11]

By blocking muscarinic receptors in the detrusor muscle, anticholinergic agents can reduce uninhibited detrusor contractions, a sequela of prolonged bladder outlet obstruction. Thus, irritative voiding symptoms are reduced. The peak clinical effect is observable in several weeks. It is recommended that a patient should be reevaluated 4 to 6 weeks after starting an anticholinergic agent for BPH. These agents do not improve urinary flow rate or consistently improve AUA symptom scores. Because older patients are sensitive to the central nervous system adverse effects and dry mouth, such patients should be started on the lowest effective dose and then slowly titrated up.[9,11] Anticholinergic agents are contraindicated in patients with narrow angle glaucoma, urinary or gastric retention, or severely decreased intestinal motility. The total anticholinergic burden should be considered prior to making the decision to initiate an anticholinergic agent if the patient is already taking other anticholinergic agents (eg, antipsychotic, antidepressant, antihistamine, antiparkinsonian agents). When multiple anticholinergic agents are taken concurrently, anticholinergic adverse effects, including dry mouth, nausea, constipation, blurred vision, and confusion, will more likely occur and be more severe.

For patients who poorly tolerate systemic anticholinergic adverse effects, options include darifenacin, which is a uroselective M_3 receptor antagonist;

anticholinergics, which preferentially inhibit M_3 receptors more than other receptors (eg, solifenacin)[62]; transdermal oxybutynin, which bypasses first-pass hepatic metabolism to an active metabolite with anticholinergic adverse effects; or extended-release formulations of anticholinergic agents (eg, tolterodine), which produce lower peak plasma concentrations as compared to immediate-release formulations. For older adults at risk of sedation and confusion from anticholinergic agents, trospium or fesoterodine has a lower propensity to cross the blood brain barrier and may be a good choice.[63]

In the presence of BPH, anticholinergic agents can cause acute urinary retention in patients with poor detrusor contractility. Therefore, before prescribing an anticholinergic agent, a PVR urine volume should be measured; it should be 100 to 150 mL or less.[9] By so doing, patients at high risk of acute urinary retention would be excluded from treatment.

β_3-Adrenergic Agonists

Approximately 95% of the β-adrenergic receptors in the urinary bladder are of the β_3 subtype. When stimulated, β_3-adrenergic receptors increase production of cyclic adenosine monophosphate (cAMP), which relaxes the detrusor muscle.[9,11]

⑨ β_3-Adrenergic agonists relax the detrusor muscle during the storage phase of the micturition cycle, thereby reducing irritative voiding symptoms, increasing urinary bladder capacity, and increasing the interval between voidings. They do not inhibit voiding or reduce urinary flow rate, nor do they increase PVR urine volume or cause acute urinary retention.[64] The clinical efficacy of these agents for LUTS is comparable to that of anticholinergic agents, but they are better tolerated. They do not produce anticholinergic adverse effects, nor do they cause acute urinary retention.

β_3-Adrenergenic agonists are indicated for symptomatic management of overactive bladder syndrome, which presents with symptoms that overlap with the irritative component of LUTS. For this reason, they are used as an alternative to anticholinergic agents in patients with LUTS, when irritative symptoms persist despite treatment with an α_1-adrenergic antagonist or 5α-reductase inhibitor.[64] The usual starting dose of mirabegron is 25 mg daily, increasing to 50 mg daily if needed. Increasing the dose to 100 mg is no more effective than 50 mg. A usual daily dose of 25 mg daily is recommended for patients with impaired renal function (creatinine clearance of 15-20 mL/min [0.25-0.33 mL/s]) or moderate hepatic impairment. Mirabegron should not be used in patients with severe hepatic dysfunction or a creatinine clearance less than 15 mL/min (0.25 mL/s).

Vibegron offers several potential advantages over mirabegron. It does not penetrate the blood brain barrier, has no significant blood pressure effects, and may be faster acting than mirabegron. For patients who have difficulty swallowing a tablet, it may be crushed and mixed with applesauce or stirred into a glass of water. Vibegron also does not cause significant interactions with cytochrome 3A4, 2D6, or 2C9.[64]

Adverse effects of mirabegron include mild headache, dry mouth, nausea, diarrhea, constipation, nasopharyngitis, and in rare cases QT-interval prolongation. None of these adverse effects cause discontinuation of treatment. Mirabegron increases systolic blood pressure by 0.5 to 1 mm Hg and heart rate by 1 bpm. Although these increases are generally small, older adults with BPH often have essential hypertension and the concern is that this may be worsened by mirabegron. Therefore, patients with uncontrolled hypertension or a systolic or diastolic blood pressure of 180 mm Hg or 110 mm Hg or higher, respectively, should avoid mirabegron. Regular blood pressure monitoring is advised in patients with poorly controlled blood pressure, significant congestive heart failure, cardiomyopathy, or patients who are 80 years of age or older.[9,11]

Combination Drug Therapy

Many drug combinations have been used for BPH. Typically, patients begin treatment with one medication and additional medications are added when LUTS does not improve or BPH symptoms worsen. To further reduce irritative voiding symptoms in a patient who is already taking an α_1-adrenergic antagonist, an anticholinergic agent, β_3-adrenergic agonist, or a phosphodiesterase type 5 inhibitor may be added.[8] When used alone, a 5α-reductase inhibitor has a slow onset of action. To achieve faster symptom relief, an α_1-adrenergic antagonist, anticholinergic agent,[65] β_3-adrenergic agonist, or a phosphodiesterase inhibitor[63,66] can be added. When any drug combination is used, the benefit of reducing bothersome symptoms must be balanced by the increased risk of adverse effects and drug interactions, higher cost of treatment, lower rates of adherence to treatment, and modest improvement in objective measures of BPH improvement.[63,65] Table 104-7 summarizes commonly prescribed combination regimens.

TABLE 104-7

Commonly Prescribed Combination BPH Regimens, Indications, and Precautions

Combination Regimen	Rationale	Comments
α_1-Adrenergic antagonist + 5α-reductase inhibitor	Moderate/severe LUTS with enlarged prostate gland of 40 g or more (or PSA >1.4 ng/mL [mcg/L])	These patients are at risk of developing complications of long-standing BPH.
α_1-Adrenergic antagonist + anticholinergic agent OR 5α-reductase inhibitor + anticholinergic agent	Moderate/severe LUTS with irritative symptoms not responding to an α_1-adrenergic antagonist alone[12] OR Moderate/severe LUTS with enlarged prostate gland of 40 g or more, and irritative symptoms	Use these combinations cautiously in patients already taking medications with anticholinergic effects/side effects. Avoid in patients with postvoid residual urine volume that is greater than 100 to 150 mL. Preferentially choose an anticholinergic agent with less likelihood to cross the blood brain barrier and cause confusion (eg, solifenacin).[14]
α_1-Adrenergic antagonist + β_3-adrenergic agonist OR 5α-reductase inhibitor + β_3-adrenergic agonist	Moderate/severe LUTS with irritative symptoms not responding to an α_1-adrenergic antagonist alone OR Moderate/severe LUTS with enlarged prostate gland of 40 g or more and irritative symptoms	Preferred regimen for patients with poor tolerance to side effects of anticholinergic agents. Do not use this combination in patients with unstable hypertension.
α_1-Adrenergic antagonist + phosphodiesterase inhibitor	Moderate/severe LUTS with irritative or obstructive symptoms not responding to an α_1-adrenergic antagonist alone[66] OR Moderate/severe LUTS with concomitant erectile dysfunction	This combination may cause hypotension. To minimize, preferentially use alfuzosin, tamsulosin, or silodosin when also prescribing tadalafil.[55]
5α-Reductase inhibitor+ phosphodiesterase inhibitor	Moderate/severe LUTS with enlarged prostate gland of 40 g or more and with irritative or obstructive symptoms not responding to a 5α-reductase inhibitor alone	The phosphodiesterase inhibitor can offset erectile dysfunction of 5α-reductase inhibitor.[9]

BPH, benign prostatic hypertrophy; LUTS, lower urinary tract symptoms.

Of all the combination medication regimens, an α_1-adrenergic antagonist plus a 5α-reductase inhibitor has been extensively studied and is recommended to use at the outset for patients with both moderate-to-severe symptoms, an enlarged prostate gland of at least 40 g and PSA of at least

1.4 ng/mL (mcg/L). Such patients are at high risk for disease progression, as evidenced by symptom worsening and development of disease complications, including acute urinary retention, recurrent urinary tract infection, or the need for surgical intervention.[67]

In the landmark Multiple Treatment of Prostate Symptoms Study (MTOPS), a combination regimen of finasteride and doxazosin for 5 years was shown to prevent symptom progression by 66%, decrease the risk of developing acute urinary retention by 81%, and decrease the need for prostate surgery by 67%. Moreover, urinary symptom improvement and higher urinary flow rates at 15 to 18 months were observed in patients treated with combination therapy, as compared with monotherapy with finasteride alone or doxazosin alone.[67] In another key clinical trial, the Combination of Avodart and Tamsulosin (COMBAT) study, dutasteride versus tamsulosin versus a combination of dutasteride and tamsulosin were evaluated in patients with prostate glands of 40 mL or greater and PSA of 1.5 ng/mL (mcg/L) or higher. The combination regimen was more effective in reducing symptoms 9 months after the start of treatment than dutasteride alone or tamsulosin alone. In addition, after a long-term follow-up of 4 years, the combination of dutasteride and tamsulosin prevented disease progression and reduced the need for prostate surgery.[68]

Although not proven by direct comparison trials, any combination of 5α-reductase inhibitor and α_1-adrenergic antagonist probably is similarly effective for patients with the aforementioned characteristics. The disadvantages of a combination regimen include increased medication cost, decreased adherence to multidrug treatment regimens, and an increased incidence of adverse drug effects (eg, sexual dysfunction).[62]

When this combination is used to prevent BPH progression, patients must continue both medications. Studies have shown if the 5α-reductase inhibitor is discontinued, LUTS recurs, and the prostate size may increase.[62] However, when the combination is used for LUTS in patients who are not at risk of BPH complications, the α_1-adrenergic antagonist may be discontinued after 6 or 9 months of continuous treatment with the 5α-reductase inhibitor.[9,11]

Surgical Interventions

⑩ The gold standard for treatment of patients with complications of BPH is prostatectomy.[9,11] Surgical intervention is indicated for patients with moderate-to-severe symptoms, who are not responsive to or cannot tolerate adverse effects of drug therapy, who are noncompliant with drug therapy, or who prefer surgical intervention. Surgical intervention is always indicated for patients with complications of BPH, including acute urinary retention not responsive to drug treatment, chronic urinary retention associated with decreased renal function or overflow urinary incontinence, urolithiasis, recurrent urinary tract infection, or recurrent hematuria.[9,11] Surgical removal of the prostatic adenoma offers the highest rate of symptom improvement, but it also has the highest complication rate.

With the availability of 5 medical treatment options for the treatment of BPH, most symptomatic patients are first managed medically. As a result, the number of surgeries for BPH has decreased significantly and the patients who are treated surgically for BPH tend to be older and more likely to have sarcopenia and/or frailty.[69–71] This has stimulated the technology development of a plethora of lasers and miniaturization of tools to expand the number and type of minimally invasive surgical procedures, which can be performed on an outpatient basis with local anesthesia, result in less blood loss, are less expensive than chronic medical treatment for BPH, and are associated with fewer adverse events than conventional prostatectomy procedures, which include transurethral resection of the prostate (TURP) or open prostatectomy.[11,70] However, all minimally invasive surgical procedures are also associated with a smaller improvement in voiding symptoms and a higher reoperation rate and shorter time to recurrence of LUTS than TURP or open prostatectomy.[11,70]

With TURP, an endoscopic resectoscope with a loop electrocautery inserted through the urethra is used to remove the inside core of the prostatic adenoma. This enlarges the opening at the bladder neck and prostatic urethra. Often performed as outpatient surgery, this procedure produces on average a peak urinary flow rate increase by 10 mL/s and improves the AUA Symptom Score by 10 to 18 points in approximately 90% of patients.[9,11] A common complication of TURP is retrograde ejaculation, occurring in up to 75% of patients. Bleeding, urinary incontinence, and erectile dysfunction occur in smaller, but significant numbers of patients (2%–15%).[70] Approximately 2% to 10% and 12% to 15% of patients require second surgeries within 5 and 8 years, respectively.[70]

A conventional open prostatectomy requires a suprapubic or perineal incision to allow the surgeon to remove the entire prostate gland. This procedure is reserved for large prostate glands of 80 to 100 g or more, and is a good choice when the patient has concurrent bladder stones or bladder diverticuli that can be corrected at the same time. Open prostatectomy is being performed laparoscopically or robotically. This procedure requires that the patient to be hospitalized. Once the entire prostate gland is excised along with the internal urethral sphincter, the urinary bladder and remaining urethra must be reconnected. The incision is stabilized by leaving an indwelling urethral catheter in place for 1 or 2 weeks. Adverse effects including bleeding, urinary and soft tissue infection, retrograde ejaculation in 77% of patients, erectile dysfunction in 16% to 33% of patients, and urinary incontinence in 2% of patients. The reoperation rate is 3% to 5% at 10 years.[9,70]

Table 104-8 lists common minimally invasive surgical procedures for BPH. Although the AUA guidelines include recommended indications for each procedure largely based on prostate gland size, additional key considerations include the availability of technology at the facility, skill and expertise of the surgeon, patient preference for one type of procedure over another, whether the patient's health insurance covers the cost of the procedure, and associated adverse effects of the procedure.

TABLE 104-8

Common Minimally Invasive Surgical Procedures for BPH

Procedure	Methodology	Indication	Comment
Transurethral incision of the prostate (TUIP)	Multiple incisions of the bladder neck widen the bladder neck to increase bladder emptying. Prostate tissue is not removed.	Best in men with small prostates 30 mL or less. Has outcomes similar to TURP.	The reoperation rate for TUIP is slightly higher than with TURP.
Prostatic urethral lift (Urolift)	Adjustable nitinol and stainless steel implants are inserted transurethrally. These implants tack open the obstructing prostate lobes and enhance bladder emptying. Prostate tissue is not removed.[71–73]	• Indicated for prostate glands that are 30 to 80 mL. • This procedure may be a good option for sexually active men as it appears to preserve erectile and ejaculatory function.[72–74]	Unsuitable for men with obstructing median lobes, prostates greater than 80 mL, or men with urinary retention.
Potassium titanyl phosphate (KTP or Green Light) Laser vaporization of the prostate	The laser is inserted transurethrally. The laser fiber vaporizes and coagulates prostate tissue. No tissue is available for pathologic analysis.	• Indicated for prostate glands that are less than 80 mL. Some prostate tissue is removed. • Laser vaporization may be preferred over TURP in patients with frailty, those taking anticoagulants, or those at risk of bleeding.[75]	
Robotic waterjet treatment (Aquablation)	• Using image guidance and robotics, a cystoscope with ablation probe is inserted transurethrally. A targeted saline jet stream resects the prostate.[75–77] • Resection time is less than 10 minutes. • The saline is not heated, which reduces thermal injury to tissue.	Indicated for prostate glands that are 30 to 80 mL. May be a good option for sexually active patients, as sexual function appears to be unaffected by the procedure.	
Water vapor thermal therapy (Rezum)	• Water vapor is heated using a bedside radiofrequency device. Vapor energy is delivered to and injected into the prostate transurethrally, and it causes cell necrosis. The	• Indicated for prostate glands that are 30 to 80 mL, or in patients with an enlarged median lobe.[70,71,78] • May be a good option for sexually	• It may take up to 3 months for peak clinical effects to be evident. This is because necrosed

	procedure includes 4 or 5 injections.[78] - This modality produces localized necrosis of the prostate without damaging the urethra since the prostatic pseudocapsule is resistant to heated water vapor.[78]	active patients, as sexual function appears to be unaffected by the procedure.	prostate tissue must be resorbed. - Avoid this procedure in patients with implanted urethral sphincters or penile prosthesis.[78]
Thulium (ThuLEP) or Holmium (HoLEP) Laser Enucleation of the Prostate	Transurethrally, a resectoscope peels the prostate away from its capsule. The prostate is morcellated in the bladder and then extracted. The laser is then used for hemostasis.	- Indicated for large prostate glands that are greater than 80 mL. Excised prostate tissue is removed and available for pathologic review. - Laser prostatectomy is preferred over conventional therapy in patients who are taking anticoagulants or have a risk of bleeding.[79,80]	

Data from Reference 70.

Phytotherapy

Although phytotherapy is widely used in Europe for the management of BPH, the published data on herbal agents are largely inconclusive and conflicting. Studies often lack placebo controls, which are essential for assessing treatments for BPH because spontaneous regression of mild symptoms can occur. Furthermore, because these agents are marketed under the Dietary Supplements Health and Education Act, their efficacy, safety, and quality are not regulated by the FDA. For these reasons, herbal products—including saw palmetto berry (*Serenoa repens*), stinging nettle (*Urtica dioica*), South African star grass (*Hypoxis rooperi*), pumpkin seed (*Cucurbita pepo*), and African plum (*Pygeum africanum*)—are not recommended for treatment of BPH.[14] Excellent reviews on phytotherapy for BPH have been published.[9,81]

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcome of BPH therapy is improvement of voiding symptoms with minimal treatment-related adverse effects. As a disease for which therapy is directed at the voiding symptoms that the patient finds most bothersome, assessment of outcomes depends on the patient's perceptions of the effectiveness of therapy. Use of a validated, standardized instrument, such as the AUA Symptom Score, for assessing patient's voiding symptoms is important in this process.[9,11] A clinically significant improvement is generally associated with a decrease in score of three points or more. The efficacy of any new medication or medication combination for treatment of BPH should be assessed 6 to 12 weeks after its start. Symptomatic improvement of LUTS is expected, although 5α-reductase inhibitors will require at least 6 months to shrink an enlarged prostate.[9,11,16]

For patients being considered for surgical treatment, objective measures of bladder emptying are useful and include the urinary flow rate and PVR urine volume (see Diagnostic Evaluation section).

Because this patient population is at high risk for prostate cancer, PSA should be measured and a digital rectal examination performed annually if a patient has a life expectancy of at least 10 years. For patients taking 5α-reductase inhibitors, a second PSA taken 6 months after the start of treatment should be compared with baseline measurements. If the patient is suspected of having developed renal impairment as a consequence of long-standing bladder outlet obstruction, then BUN and serum creatinine should be evaluated at regular intervals.

CONCLUSION

A ubiquitous disease of aging men, symptomatic BPH requires medical attention to preserve the patient's quality of life and to prevent disease complications, many of which can be life-threatening in this patient population. In men who have no or mildly bothersome symptoms, watchful waiting and behavior modification are the best treatment approach, as BPH remains stable or even regresses in approximately half of these men.

For patients with voiding symptoms that are moderately to severely bothersome, pharmacotherapy is indicated. An α_1-adrenergic antagonist is the agent of first choice. Second-generation agents include terazosin, doxazosin, and alfuzosin, and third-generation agents include tamsulosin and silodosin. Immediate-release formulations of terazosin and doxazosin cause more cardiovascular adverse effects than do extended-release formulations (eg, doxazosin or alfuzosin), or uroselective α_{1A}-adrenergic agents (eg, tamsulosin, silodosin, or alfuzosin). 5α-Reductase inhibitors are preferred drug treatment for patients with enlarged prostates greater than 40 g who poorly tolerate the hypotensive adverse effects of α_1-adrenergic antagonists. However, 5α-reductase inhibitors have a slow onset of action. For patients who do not respond to monotherapy, combination drug therapy could be attempted.

The combination of 5α-reductase inhibitor and α_1-adrenergic antagonist is well established for patients at high risk of developing complications of BPH. In this subset of patients, continuous use of both medications is necessary.

For patients with both moderate-to-severe LUTS and erectile dysfunction, a phosphodiesterase inhibitor alone or combined with an α-adrenergic antagonist may be prescribed. For patients with moderate-to-severe LUTS with a predominance of irritative voiding symptoms, an anticholinergic agent, mirabegron, or a phosphodiesterase inhibitor may be added to an existing drug treatment regimen for BPH. Before starting an anticholinergic agent in a patient with BPH, the patient's PVR should be less than 100 to 150 mL.

For patients who do not respond to or cannot tolerate adverse effects of medical therapy, or who have complications of BPH, surgery is required. Although it has more adverse complications than pharmacotherapy or watchful waiting, TURP is considered the gold standard. Minimally invasive surgical procedures are an attractive alternative for older patients with frailty, as the procedures can be performed on an outpatient basis using local anesthesia. The risk of serious adverse effects are less with a minimally invasive surgical procedure than with TURP.

ABBREVIATIONS

ALLHAT	Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial
AUA	American Urological Association
BPE	benign prostatic enlargement
BPO	benign prostatic obstruction
BPH	benign prostatic hyperplasia
BUN	blood urea nitrogen
cAMP	cyclic adenosine monophosphate
cGMP	cyclic guanosine monophosphate
COMBAT	Combination of Avodart and Tamsulosin (Study)
CYP	cytochrome P-450
DHT	dihydrotestosterone
GI	gastrointestinal
IPSS	International Prostate Symptom Score
LUTS	lower urinary tract symptoms
MTOPS	Multiple Treatment of Prostate Symptoms (Study)
PSA	prostate-specific antigen
PVR	postvoid residual (pertains to urine volume)
REDUCE	Reduction by Dutasteride in Prostate Cancer Events
TURP	transurethral resection of the prostate
TUIP	transurethral incision of the prostate

SELF-ASSESSMENT QUESTIONS

1. A patient complains of LUTS despite treatment with silodosin 8 mg daily for 1 month. The patient's AUA symptom index was 30 at baseline and is now 29. Which of the following statements is a correct interpretation of the change in the AUA symptom index?

   A. The reduction in the AUA symptom score is considered clinically significant.

   B. The patient probably didn't answer the AUA symptom index questions correctly, which explains why he is still complaining of LUTS.

   C. Based on the patient's current AUA symptom index, the patient requires a prostatectomy.

   D. The patient's current AUA symptom score indicates that the patient has mild symptoms.

   E. Based on the data provided, silodosin is ineffective in this patient.

2. Which of the following statements about α_1-adrenergic antagonists is correct?

   A. The daily dose of silodosin should be increased when the creatinine clearance is less than 30 mL/min (0.5 mL/s).

   B. Extended-release doxazosin is more likely to cause ejaculatory dysfunction than immediate-release terazosin.

   C. Concurrent use of silodosin with antihypertensives is not recommended.

   D. Prazosin is not recommended for BPH because it must be taken two to three times a day.

E. Uptitrating the dose of alfuzosin over 2 to 3 weeks is essential for clinical effectiveness.

3. Which one of the statements about α_1-adrenergic antagonists and floppy iris syndrome is correct?

   A. Only tamsulosin has been associated with this adverse effect.

   B. Vision loss is typically painful and affects both eyes.

   C. A hallmark of this side effect is small pupils that are not responsive to mydriatic agents.

   D. α_1-Adrenergic antagonists should be stopped 4 weeks before cataract surgery.

   E. Cataract surgery is a contraindication for α_1-adrenergic antagonist use.

4. What is the appropriate minimum length of a clinical trial of a 5α-reductase inhibitor?

   A. 3 to 6 hours

   B. 3 to 6 days

   C. 6 to 12 weeks

   D. 6 to 12 months

   E. 3 to 6 years

5. Which one of the following statements about combination therapy using a 5α-reductase inhibitor and an α_1-adrenergic antagonist for BPH is correct?

   A. The combination produces fewer adverse effects that using either drug alone.

   B. The combination is indicated in patients with a prostate gland size of 15 g or less and moderate-to-severe LUTS.

   C. LUTS responds quicker to the combination than to either drug used alone.

   D. Combination therapy delays disease progression and reduces the need for surgery.

   E. Combination therapy, but not either drug alone, increases the risk of high-grade prostate cancer.

6. Which one of the following medications can worsen LUTS?

   A. Hydrochlorothiazide

   B. Aspirin

   C. Prednisone

   D. Irbesartan

   E. Cephalexin

7. A patient has a urinary flow rate of 8 mL/s, AUA symptom index of 20, a PVR of 0 mL, and a prostate gland size of 20 g. He complains of nocturia three times/night and poor quality sleep. The best management approach is:

   A. Watchful waiting

B. An α_1-adrenergic antagonist

C. A 5α-reductase inhibitor

D. A combination of an α_1-adrenergic antagonist and a 5α-reductase inhibitor

E. A combination of tolterodine plus an α_1-adrenergic antagonist

8. A 60-year-old patient has moderate LUTS due to BPH and erectile dysfunction. He is sexually active. The best management approach is

A. Watchful waiting

B. An α_1-adrenergic antagonist

C. A 5α-reductase inhibitor

D. A phosphodiesterase type 5 inhibitor

E. A combination of an α-adrenergic antagonist and a 5α-reductase inhibitor

9. For patients with BPH and essential hypertension, treating both conditions with a single α_1-adrenergic antagonist is not recommended because patients would be at increased risk of

A. Metabolic syndrome

B. Congestive heart failure

C. Diabetes mellitus

D. Renal failure

E. Liver failure

10. When used for BPH, trospium

A. Reduces the size of an enlarged prostate gland

B. Halts disease progression

C. Reduces irritative voiding symptoms

D. Decreases PSA levels

E. May decrease PVR

11. When used for LUTS, vibegron

A. Halts disease progression

B. Reduces irritative voiding symptoms

C. Reduces obstructive voiding symptoms

D. Decreases PSA levels

E. May increase PVR

12. When counseling a patient taking silodosin, which one of the following instructions is correct?

    A. Take each dose after the same meal each day.

    B. Start with 1 mg/day and slowly titrate up over several weeks.

    C. This drug should not be taken with nitrates.

    D. This drug can be taken in divided doses during the day.

    E. This drug works on the bladder to reduce voiding symptoms.

13. A patient with BPH has an AUA symptom score of 30, complains of LUTS, and has a prostate size of 35 g. The best choice treatment is:

    A. Watchful waiting

    B. An α_1-adrenergic antagonist

    C. A 5α-reductase inhibitor

    D. A combination of an α-adrenergic antagonist and a 5α-reductase inhibitor

    E. A prostatectomy

14. Which one of the following statements is true about drug treatment for BPH?

    A. Alfuzosin inhibits 5α-reductase.

    B. Terazosin selectively inhibits α_{1A}-adrenergic receptors.

    C. A medication must shrink the prostate to be effective for BPH.

    D. All of the α_1-adrenergic antagonists are equally effective.

    E. An effective treatment will lower the peak urinary flow rate.

15. For which one of the following conditions in a patient with BPH should an anticholinergic agent be avoided?

    A. Urinary flow rate of 20 mL/s

    B. Essential hypertension

    C. Prostate gland of 30 g

    D. A history of diabetes mellitus

    E. A postvoid residual urine volume of 250 to 300 mL or more

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** A three-point decrease in AUA symptom index is considered clinically significant. This patient has only a one point change in AUA symptom index which suggests that silodosin is ineffective. See the Desired Outcomes section.

2. **D.** Prazosin is a second-generation α_1-adrenergic antagonist, like terazosin and doxazosin. It has a short half-life and has to be taken 2 to 3 times a day. For this reason, it is not recommended for BPH by the American Urological Association. See the Second-Generation α1-Adrenergic Antagonists section.

3. **C.** Floppy iris syndrome is characterized by small pupils, a billowing iris, and increased intraoperative complications during cataract surgery. See the Adverse effects (α1-Adrenergic Antagonists) section.

4. **D.** Although LUT and urinary flow rate may show earlier improvement, maximum prostate shrinkage may take 6 months. See the 5α-Reductase Inhibitors section.

5. D. Combination therapy may delay BPH progression and reduce the need for prostate surgery, but it causes more adverse effects than treatment with one drug. It should be reserved for symptomatic patients at risk for BPH complications, which includes patients with an enlarged prostate of 40 g or more. See the Combination Drug Therapy section.

6. **A.** Hydrochlorothiazide is a diuretic, which causes polyuria. This can worsen LUTS. See the Medication-Related Symptoms section.

7. **B.** A patient with moderate BPH with minimal enlargement of the prostate should be treated with an α_1-adrenergic antagonist. See the Pharmacologic Therapy section.

8. **D.** An ideal candidate for tadalafil has both moderate BPH and erectile dysfunction. The two conditions can be treated with one medication. See the Pharmacologic Therapy section

9. **B.** Based on the ALLHAT study, use of an α_1-adrenergic antagonist alone for treatment of essential hypertension can produce more congestive heart failure than amlodipine, lisinopril, or chlorthalidone. Therefore, in a patient with BPH and essential hypertension, the use of an α_1-adrenergic antagonist to treat both conditions is not recommended. See the Second-Generation α1-Adrenergic Antagonists section.

10. **C.** Anticholinergics relax the detrusor muscle, thereby inhibiting involuntary detrusor contractions. This decreases irritative voiding symptoms. See the Anticholinergic Agents section.

11. **B.** Vibegron relaxes the detrusor muscle, thereby inhibiting involuntary detrusor contractions. This decreases irritative voiding symptoms. See the β3-Adrenergic Agonists section.

12. **A.** Food decreases the oral bioavailability of silodosin, which is beneficial, in so far as this food-drug interaction helps decrease peak serum concentrations of tamsulosin. This decreases the drug’s effect on blood pressure. Therefore, it is recommended that silodosin should be taken after the same meal each day. See the Third-Generation α1-Adrenergic Antagonists section.

13. **D.** The patient with an enlarged prostate and severe symptoms is an ideal candidate for combination therapy. This approach will relieve LUTS quickly and also shrink an enlarged prostate. See the Combination Drug Therapy section.

14. **D.** The α_1-adrenergic antagonists differ only in side effects. They are considered equally effective. See the α1-Adrenergic Antagonists section.

15. **E.** Anticholinergics are contraindicated in patients with a postvoid urine residual volume of 250 to 300 mL. In such patients, an anticholinergic agent may cause acute urinary retention. See the Anticholinergic Agents section.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 105: Urinary Incontinence

Eric S. Rovner; Kristine Talley; Sum Lam

KEY CONCEPTS

KEY CONCEPTS

①In evaluating urinary incontinence (UI), drug-induced or drug-aggravated etiologies must be ruled out.

②Accurate diagnosis and classification of UI type are critical to the selection of appropriate pharmacotherapy.

③Goals of treatment for UI are reduction of symptoms, minimization of adverse effects, and improvement in quality of life.

④Nonpharmacologic, nonsurgical treatment is the first-line treatment for several types of UI, and should be continued even when drug therapy is initiated.

⑤Antimuscarinic agents are second-line treatments for urgency incontinence. Choice of agent should be based on patient characteristics (eg, age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen).

⑥β_3-Adrenergic agonists (mirabegron, vibegron) can be considered in patients who failed to achieve optimal efficacy or cannot tolerate adverse effects of antimuscarinic agents.

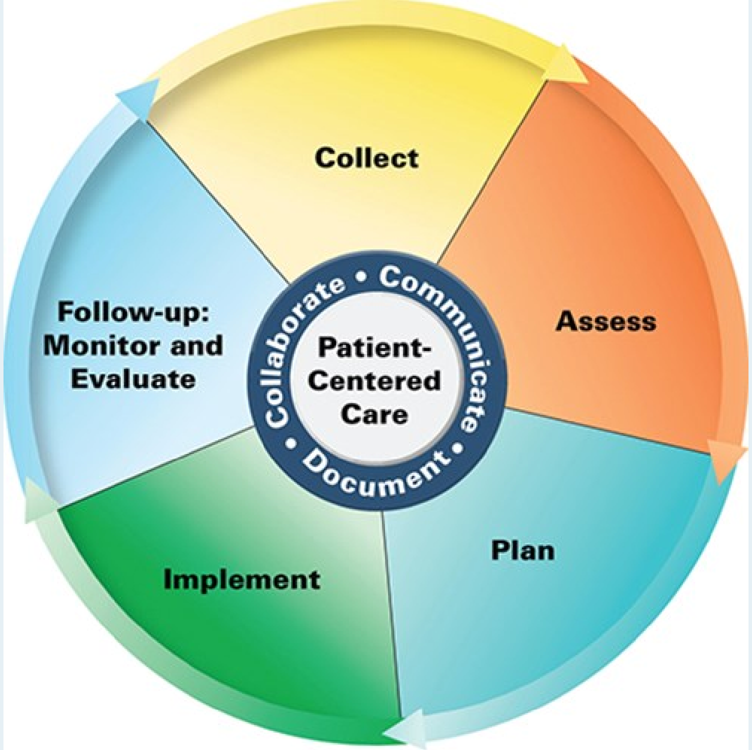
⑦Duloxetine (approved in Europe only), α-adrenergic receptor agonists, and topical (vaginal) estrogens (alone or together) are the drugs of choice for urethral underactivity (stress urinary incontinence).

⑧Assessment of patient outcomes should include efficacy, adverse effects, adherence, and quality of life.

⑨Management of UI should target individualized goals and treatment preferences, which may change over time. If therapeutic goals are not achieved with a given agent at optimal dosage for an adequate duration of trial, consider switching to an alternative agent and/or surgery.

PATIENT CARE PROCESS

Patient Care Process for Urinary Incontinence



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status, drug allergy profile)
- Patient medical and genitourinary surgical history including coexisting conditions that may influence UI
- Obstetric and menstrual history in women
- Past conservative, medical, and surgical treatment of UI
- Social history (tobacco/ethanol use; caffeine and fluid intake; environmental issues; exercise; availability of family caregiver, if relevant)
- Current medications (see Table 105-1) including over-the-counter (OTC), herbal products, and dietary supplements
- Objective data
    - Lab tests: urinalysis ± urine culture; if infected, treat and reassess if appropriate
    - Cough stress test to demonstrate stress UI (if appropriate)
    - Postvoid residual urine by bladder ultrasound or catheterization (if suspected urinary retention/overflow incontinence)

Assess

- Urinary symptoms including bladder diary (see Table 105-2)
- Presence of bowel symptoms or vaginal prolapse symptoms (in women); estrogen status in women
- Quality of life, treatment preferences, and goals
- Mental status, body mass index, physical dexterity, and mobility
- Abdominal, rectal, prostate (in men), neurological, and pelvic examination (in women)

Plan*

- Nonpharmacological interventions based on UI severity and subtype (see Table 105-3)
- Drug therapy regimen for urgency UI, if indicated (see Table 105-5)
- Monitoring parameters (see Tables 105-6 and 105-7); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug-specific information)
- Self-monitoring for resolution of UI symptoms and drug adverse events (if indicated)
- Referrals to other providers when appropriate (eg, urologist, urogynecologist, continence nurse practitioner, physical therapist)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, adherence assessment, treatment response)

Follow-up: Monitor and Evaluate

- Monitor for patient response in 1 or 2 weeks after therapy initiation
- Assess efficacy after a minimum of 4 weeks to assess drug efficacy
- Resolution of UI symptoms
- Presence of adverse effects (eg, Table 105-7), or drug interactions
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate efficacy and necessary duration of therapy every 3 to 6 months

Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Watch one of the two videos titled “Taking Control of Overactive Bladder (OAB)” by the Urology Care Foundation. Reflect on the impact of OAB from the patient’s perspective. Available at: https://www.urologyhealth.org/urology-a-z/o/overactive-bladder-(oab)

Next, develop a table with two columns, one titled antimuscarinic agents and one titled β_3-adrenergic agonists. In each column, identify one drug that represents the drug class. Compare the advantages and disadvantages of these two agents when used for the treatment of OAB (efficacy, dosage form, dosing, side effects, drug interactions, drug cost, etc.).

INTRODUCTION

Urinary incontinence (UI) is defined as involuntary loss of urine.[1] It is frequently accompanied by other bothersome lower urinary tract symptoms, such as urgency, increased daytime frequency, and nocturia. It is one of the most common health conditions occurring in adults, and yet it is an underdetected and under-reported problem that can significantly affect quality of life. Patients with UI may have depression as a result of the perceived lack of self-control, loss of independence, and lack of self-esteem, and they often curtail their activities for fear of an “accident.” UI may also have serious medical and economic ramifications for untreated or undertreated patients, including perineal dermatitis, worsening of pressure ulcers, urinary tract infections, and falls.

This chapter highlights the epidemiology, etiology, pathophysiology, treatment of stress, urgency, mixed, and overflow UI in men and women.

Editors’ note: In this and other chapters in Pharmacotherapy, references to biologic gender (as assigned at birth) are used based on prior literature being discussed or anatomical or physiologic differences. We recognize that not all individuals identify with their gender at birth, and to the degree possible when discussing therapeutics, we avoid use of references to gender. In this chapter on Urinary Incontinence, “men” and “women” are used in discussing prior studies, published guidelines, and other recommendations for diagnosis and treatment based on biological gender and do not necessarily reflect an individual’s gender identity.

EPIDEMIOLOGY

UI is highly prevalent, and the impact of this condition is substantial, crossing all racial, ethnic, and geographic boundaries. In addition, lower urinary tract symptoms (eg, urgency, urinary frequency, and nocturia) associated with OAB are also quite debilitating. Evidence from several studies indicates that UI is associated with reduced levels of social and personal activities, increased psychological distress, and overall decreased quality of life.[2] The condition can affect people of all age groups, but the peak incidence of UI, at least in women, occurs around the age of menopause, with a slight decrease in the age group 55 to 60 years, and then a steadily increasing prevalence after the age of 65 years.

Globally, the prevalence of UI ranges between 25% and 45%.[3] Determining the true prevalence of UI is difficult because of problems with definition, reporting bias, and other methodological issues. The condition is stigmatizing as it is associated with considerable embarrassment, as well as real or perceived loss of self-control. Such perceptions may lead to a decrease in reporting, especially self-reporting. Prevalence estimates vary by age, gender, and racial/ethnic group, setting (noninstitutionalized vs institutionalized), and incontinence subtype (stress, urgency, mixed, and overflow UI). Prevalence tends to be highest in women, those of advanced age, and living in long-term care settings.[2] Globally, women have three times the prevalence of urinary incontinence than men. The prevalence of incontinence increases as women age. Ten percent of adult women have incontinence, but this prevalence increases to 40% for women aged 70 years and older.[3] The National Health and Nutrition Examination Survey (NHANES) reported a prevalence rate of 43.8% in noninstitutionalized adults aged 65 years and over, with more than half of women and one-quarter of men reporting urine leakage.[2] Twelve percent of older women had severe or very severe scores on a validated incontinence severity index representing daily urine leakage with more than drops or small splashes, whereas, older men had slight or moderate incontinence scores representing less-frequent urine leakage.[2]

Relatively little is known about differences in clinical and epidemiologic characteristics of incontinence across racial or ethnic groups, especially in men. Almost all population-based studies comparing UI prevalence across racial and ethnic groups is from the United States which limits generalizability. The majority of studies report that White women have a higher prevalence of UI overall and stress UI.[4] There is less consistency regarding prevalence of UI subtypes in Black women. In the BACH study, Black women had higher rates of mixed UI,[5] and in the EPI study, Black women had higher rates of urgency UI.[6] Using data from the NHANES program, no racial or ethnic differences were found in UI prevalence in men.[7] However, differences in access to healthcare as well as cultural attitudes and more may contribute to these differences.[8,9] Importantly, there are considerable differences in the causes and treatments of UI between genders.

UI prevalence is highest in nursing home residents, with 36.7% of short-stay residents and 70.3% of long-term residents having bladder control problems.[2] Residents who were aged 85 years and more compared to those aged 65 to 74 years had rates 1.5 times higher for short-term residents and 1.2 higher for long-term residents. UI is associated with several other medical conditions, such as falls,[10] urinary tract infection, skin breakdown, sexual function, and depression.

ETIOLOGY AND PATHOPHYSIOLOGY

Anatomy

The lower urinary tract consists of the bladder, urethra, urinary or urethral sphincter, and surrounding musculofascial structures, including connective tissue, nerves, and blood vessels. The urinary bladder is a hollow organ composed of smooth muscle and connective tissue located deep in the bony pelvis in men and women. The urethra is a hollow tube that acts as a conduit for urine flow out of the bladder. An epithelial cell layer termed the *urothelium*, which is in constant contact with urine, lines the interior surface of both the bladder and the urethra. Previously considered inert and inactive, the urothelium may play an active role in the pathophysiology of many lower urinary tract disorders, including interstitial cystitis/bladder pain syndrome and UI[11] and may be a targeted location for future pharmacologic therapeutic interventions for some types of lower urinary tract dysfunction.[12] The urinary or urethral sphincter is a combination of smooth and striated muscle within and surrounding the proximal portion of the urethra adjacent to the bladder. In the male, the prostate gland lies just beyond the bladder outlet and is intimately associated with the urethral sphincter. Its location accounts for both the favorable effects of pharmacological manipulation on male lower symptoms as well as the risk of UI in males following some types of prostate surgery.

To understand the principles of pharmacotherapy for UI, an understanding of the neuroanatomy and neurophysiology of the bladder and urethra is needed. The primary motor (efferent) input to the detrusor muscle of the bladder is parasympathetic and travels along the pelvic nerves emanating from spinal cord segments S2 to S4. Pharmacologic as well as nonpharmacologic stimulation, modulation, or blockade of afferent and efferent neural pathways between the spinal cord and the lower urinary tract by various mechanisms are important options for treatment for some types of urinary incontinence. Acetylcholine is the primary neurotransmitter at the neuromuscular junction in the human lower urinary tract. Both volitional and involuntary detrusor contractions are mediated by activation of postsynaptic muscarinic receptors by acetylcholine. Of the five known subtypes of muscarinic receptors, the majority of bladder smooth muscle cholinergic receptors are of the M_2 variety. In humans, the ratio of M_2/M_3 receptor numbers is approximately 3:1. However, M_3 receptors are the subtypes responsible for both emptying contractions of normal micturition as well as involuntary bladder contractions that may result in UI.[11] Thus, most pharmacologic antimuscarinic therapy is primarily anti-M_3 based. Administration of such agents results in detrusor smooth muscle relaxation and a reduction of bladder overactivity.

β_3-Adrenergic receptors are found in the lower urinary tract at the level of the detrusor muscle and the urothelium.[11] Although found elsewhere, stimulation of these receptors in the detrusor results in smooth muscle relaxation. Clinically, administration of β_3-agonists is associated with attenuation of bladder contractility and, similar to antimuscarinics, it is used clinically to treat overactive bladder (OAB) and related urgency incontinence. β-Receptors are also located on the urethra but their clinical significance is considered to be negligible.

Clinically relevant α-adrenergic receptors are located at the level of the bladder outlet on the smooth and striated muscle of the urethra.[11] Stimulation of these receptors with α-adrenergic agonists results in increased urethral closure pressure. Such effects are usually not pronounced enough to treat stress urinary incontinence (SUI); however, the use of these agents may result in unwanted adverse effects such as aggravation of bladder outlet obstruction and result in poor bladder emptying (urinary retention), especially in men.

Other potentially relevant motor and sensory pathways, neurotransmitters, and receptors have been identified in the lower urinary tract (eg, transient receptor potential channels, E-series prostaglandin receptors). However, the exact role of such targets, as well as ways of modulating their activity pharmacologically in humans has yet to be elucidated and further discussion is beyond the scope of this chapter.

Urinary Continence

To prevent incontinence during the bladder filling and storage phase of the micturition cycle, the urethra, or more accurately the urethral sphincter, must maintain adequate closure in order to resist the flow of urine from the bladder at all times until voluntary voiding is initiated. Urethral closure or resistance to flow is maintained to a large degree by the proximal (under involuntary control) and distal (under both voluntary and involuntary control) urinary sphincters. Variable contributions to urethral closure may also come from the urethral mucosa, submucosal spongy tissue, and the overall length of the urethra. During bladder filling and urinary storage, the bladder accommodates increasing volumes of urine flowing in from the upper urinary tract without a significant increase in bladder (intravesical) pressure. The maintenance of a low intravesical pressure despite increasing volumes of urine is a unique property of the bladder and is termed *compliance*. In addition, bladder or detrusor smooth muscle activity is normally suppressed during the filling phase by centrally mediated neural reflexes. Normal bladder emptying occurs with opening of the urethral sphincters concomitant with a volitional bladder contraction. Bladder contraction occurs in a coordinated fashion, resulting in a rise in intravesical pressure. The rise in intravesical pressure is ideally of adequate magnitude and duration to empty the bladder to completion. Opening and funneling of the bladder outlet results in urine flow into the urethra until the bladder is emptied to near completion.

The bladder and urethra normally operate in unison during the bladder filling and storage phase, as well as the bladder emptying phase of the micturition cycle. The smooth and striated muscles of the bladder and urethra are organized during the micturition cycle by a number of reflexes coordinated at the pontine micturition center in the midbrain. Disturbances in the neural regulation of micturition at any level (brain, spinal cord, or pelvic nerves) often lead to characteristic changes in lower urinary tract function that may result in UI.[13,14]

Mechanisms of Urinary Incontinence

Simply stated, UI may occur as a result of abnormalities of only the urethra (including the bladder outlet and urinary sphincter) or only the bladder or as a combination of abnormalities in both. Abnormalities may result in either overactivity or underactivity of the bladder and/or urethra, with resulting development of UI. Although this simple classification scheme excludes extremely rare causes of UI such as congenital ectopic ureters and urinary fistulas, it is useful for gaining a working understanding of the condition and understanding the basis for therapeutic intervention including pharmacotherapy of various lower urinary tract disorders.

Urethral Underactivity (SUI)

Stress urinary incontinence is defined as the involuntary loss of urine on effort or physical exertion (including sporting activities) or on sneezing or coughing.[1] The pathophysiology of SUI is related to decreased or inadequate urethral closure forces. In individuals with SUI, the muscular tissues surrounding the urethra that form the urethral sphincter are compromised and thus not able to resist the expulsive forces resulting from transient increases in intra-abdominal pressure during physical activity. Such forces are transmitted to the bladder (an intra-abdominal organ), compressing it to such an extent as to cause the egress of urine through the urethra. SUI is characterized by episodic, usually low-volume urinary leakage but is clearly proportional to the amount of physical exertion or other increases in abdominal pressure such as that related to coughing and sneezing as well as the ambient urethral closure forces.

Risk factors for SUI in woman include pregnancy, childbirth, menopause, cognitive impairment, obesity, and aging.[15] In men, SUI is most commonly the result of prior lower urinary tract surgery and injury to the sphincter mechanism within and external to the urethra. Radical prostatectomy for treatment of adenocarcinoma of the prostate and transurethral resection of the prostate (TURP) is probably the most common proximate causes of SUI in the male. Notably, compared with its prevalence in women, SUI in men is actually quite rare.

SUI may be caused or aggravated by some pharmacologic agents such as α-antagonists and angiotensin-converting enzyme (ACE) inhibitors.[16] α-Antagonists may relax the smooth muscle at the level of the urethral sphincter, resulting in a weakened closure mechanism and the onset of SUI. Alternatively, some α-agonists, such as those used clinically for nasal congestion or weight loss, may improve SUI in some individuals, and may even potentially aggravate some types of voiding problems such as those related to bladder outlet obstruction from an enlarged prostate. An adverse effect of some ACE inhibitors is chronic cough, which can also aggravate existing SUI.

Bladder Overactivity (Urgency Urinary Incontinence [UUI])

Urgency UI is defined as the involuntary loss of urine associated with urgency.[1] This is most often related to detrusor (bladder) overactivity due to involuntary bladder contractions. Bladder overactivity describes the condition in which the detrusor muscle contracts inappropriately during urinary storage that, in the neurologically normal individual, results in a sense of urinary urgency. Overactive bladder is a symptom syndrome characterized by urinary urgency, usually accompanied by increased daytime frequency and/or nocturia, with urinary incontinence (OAB-wet) or without (OAB-dry), in the absence of urinary tract infection or other detectable diseases.[1] The terms *overactive bladder* and *detrusor (bladder) overactivity* are distinct and should not be used interchangeably.

Increased *frequency* is defined as the complaint that micturition occurs more frequently during waking hours than previously deemed normal; numerically, it is often quantified as more than 8 times per day. *Urgency* is described as a sudden compelling desire to urinate that is difficult to defer.[1] People with OAB typically have to empty their bladder frequently, and, when they experience a sensation of urgency, they may leak urine if they are unable to reach the toilet quickly. Many patients have associated nocturia (>1 micturition per night) and/or nocturnal incontinence (enuresis). Patients with urgency urinary incontinence (UUI) often, but invariably, experience high-volume urine leakage when it occurs. Although detrusor overactivity may be related to OAB, the former diagnosis requires urodynamic testing while the latter is symptomatically defined.

Most patients with OAB and UUI have no identifiable underlying etiology and thus are classified as "idiopathic." Patients with a combination of a relevant neurologic condition and UI related to involuntary bladder contractions demonstrated on urodynamic testing are classified as having neurogenic detrusor overactivity. Clearly identifiable risk factors for UUI include normal aging, neurologic disease (including stroke, Parkinson's disease, multiple sclerosis, and spinal cord injury), and bladder outlet obstruction resulting in pathological changes to the detrusor muscle (eg, due to benign prostatic hyperplasia [BPH] or prostate cancer).[4]

The pathophysiology of OAB and UUI is not well understood but is likely related to either neurogenic or myogenic factors or a combination of both.[1] A full discussion of these differences is complex and beyond the scope of this chapter. However, in practice, although the cause of UUI is difficult to define, the treatment is identical regardless of etiology and pathophysiology.

Some pharmacologic agents may cause or aggravate UUI. Diuretics will cause the rapid accumulation of urine in the bladder with resulting urinary urgency and frequency that can result in UUI. Alcohol will have similar effects. Anticholinesterase inhibitors may also produce urgency and frequency.

Urethral Overactivity and/or Bladder Underactivity (Overflow Incontinence)

Overflow incontinence is urinary leakage resulting from an overfilled and distended bladder that is unable to empty. This type of UI occurs when the bladder is filled to capacity at all times but is unable to empty, causing urine to leak from a distended bladder past a normal or even overactive sphincter. Another term related to overflow incontinence is *chronic urinary retention*.[1]

Overflow incontinence is the result of urethral overactivity, bladder underactivity, or a variable combination of both. Clinically and practically, the most common causes of urethral overactivity in men are anatomic urethral obstruction, including that due to BPH and prostate cancer. In women, urethral overactivity is rare but may result from cystocele formation (with resultant kinking or obstruction of the urethra) or surgical overcorrection following surgery for the repair of SUI (iatrogenic obstruction). In both men and women, overflow UI may be associated with systemic neurologic dysfunction or diseases, such as spinal cord injury or multiple sclerosis.

Bladder underactivity occurs as a result of the detrusor muscle of the bladder becoming suddenly or progressively weakened and eventually losing the ability to voluntarily contract and expel urine during voiding. In the absence of adequate contractility, the bladder is unable to empty completely, and large volumes of residual urine are left after voiding. Both myogenic and neurogenic factors have been implicated in producing the impaired contractility seen in this condition. Clinically, overflow incontinence is most commonly seen in the setting of long-term chronic bladder outlet obstruction in men, such as that due to BPH or prostate cancer, diabetes mellitus, or denervation due to radical pelvic surgery, such as abdominopelvic resection or radical hysterectomy.

① Many commonly used medications may precipitate or aggravate existing voiding dysfunction and UI (Table 105-1).[17] Agents that increase urethral resistance or closure pressure include α-agonists and tricyclic antidepressants. Over-the-counter cold and cough remedies as well as diet pills may contain agents with α-adrenergic properties and/or antihistaminic properties that can result in voiding dysfunction and urinary retention. Agents that can decrease bladder contractility include anticholinergics, tricyclic antidepressants, calcium channel blockers, narcotic analgesics, and antipsychotics.

TABLE 105-1

Medications That Influence Lower Urinary Tract Function

Medication	Effect
Diuretics, acetylcholinesterase inhibitors	Polyuria resulting in urinary frequency, urgency
α-Receptor antagonists	Urethral muscle relaxation and stress urinary incontinence
α-Receptor agonists	Urethral muscle contraction (increased urethral closure forces) resulting in urinary retention (more common in men)
Calcium channel blockers	Urinary retention due to reduced bladder contractility
Narcotic analgesics	Urinary retention due to reduced bladder contractility
Sedative hypnotics	Functional incontinence caused by delirium, immobility
Antipsychotic agents	Anticholinergic effects resulting in reduced bladder contractility and urinary retention
Anticholinergics	Urinary retention due to reduced bladder contractility
Antidepressants, tricyclic	Anticholinergic effects resulting in reduced bladder contractility (urinary retention), and α-antagonist effects resulting in reduced urethral smooth muscle contraction (stress incontinence)
Alcohol	Polyuria resulting in urinary frequency, urgency
ACEIs	Cough as a result of ACEIs may aggravate stress urinary incontinence

ACEIs, angiotensin-converting enzyme inhibitors.

Mixed Incontinence and Other Types of Urinary Incontinence

Various types of UI may coexist in the same patient. The combination of bladder overactivity resulting in urinary incontinence (urgency UI) and urethral underactivity resulting in urinary incontinence (SUI or stress UI) is termed *mixed incontinence*. The diagnosis is often difficult because of the confusing array of presenting symptoms. Bladder overactivity may also coexist with impaired bladder contractility. This occurs most commonly in the elderly and is termed *detrusor hyperactivity with impaired contractility.*[1]

Functional incontinence (also known as disability-associated urinary incontinence) is not caused by bladder- or urethra-specific factors. It occurs in the presence of a functional inability to reach a toilet or urinal in time because of a physical or mental impairment, such as cognitive or mobility deficits. It is linked to the primary disease process more than any extrinsic or intrinsic deficit of the lower urinary tract. An example of functional incontinence occurs in patients after orthopedic surgery. Following extensive orthopedic reconstructions such as total hip arthroplasty, patients are often immobile secondary to pain or traction. Therefore, patients may be unable to access toileting facilities in a reasonable amount of time and may become incontinent as a result. Treatment of this type of UI may involve simple interventions such as placing a urinal or commode at the bedside that allows for uncomplicated access to toileting. Pharmacologically, functional incontinence can be induced by sedative-hypnotics, narcotic analgesics, and other medications with cognitive adverse effects.

Many localized or systemic illnesses may result in UI because of their effects on the lower urinary tract or the surrounding structures:

1. Dementia/delirium
2. Depression
3. Urinary tract infection (cystitis)
4. Postmenopausal atrophic urethritis or vaginitis
5. Diabetes mellitus
6. Neurologic disease (eg, stroke, Parkinson's disease, multiple sclerosis, spinal cord injury)
7. Pelvic malignancy
8. Constipation
9. Congenital malformations of the urinary tract

Generally, stress UI is considered the most common type of UI and probably accounts for at least a portion of UI in more than half of all incontinent women. Some studies have found that mixed UI (stress UI and urgency UI) is the most common type of UI. However, the proportions of SUI, UUI, and mixed UI vary considerably with age group and gender of patients studied, study methodology, and a variety of other factors.

CLINICAL PRESENTATION

② UI may present in a number of ways, depending on the underlying pathophysiology. A complete medical and medication history, including an assessment of symptoms and a physical examination, is essential for correctly classifying the type of incontinence and thereby assuring appropriate therapy.

Urine Leakage

UI represents a spectrum of severity in terms of both volume of leakage and degree of bother to the patient. Carefully consider the level of patient discomfort and bother when discussing urine leakage as each individual may or may not desire therapy. A careful and complete history during the patient interview is essential to accurately determine the precise nature of the problem. The onset, nature, timing, and volume of incontinence are recorded as is the use of pads. Use of absorbent products, such as panty liners, pads, or briefs, is an important point of discussion, but the clinician must keep in mind that the use of these products varies among patients. The number and type of pads may not relate to the amount or type of incontinence, as their use is a function of personal preference and hygiene. A high number of absorbent pads may be used every day by a patient with severe, high-volume UI or, alternatively, by a fastidiously hygienic patient with low-volume leakage who simply changes pads often to prevent wetness or odor. Nevertheless, a large number of pads that are described by the patient as "soaked" is indicative of high-volume urine loss.

Regardless of the volume of urine loss, the desire to seek evaluation for UI in the majority of patients is most commonly elective and therapy is often contingent on the degree of bother to the individual patient. As with the use of absorbent products, patients differ with regard to the amount of urine loss they will tolerate before considering the condition bothersome enough to seek assistance. However, it is critically important that in some individuals new-onset UI may be the first manifestation of an undiagnosed illness (eg, diabetes, multiple sclerosis), or may occur as a result of treatment or drug therapy of an unrelated condition. It is these individuals who mandate a full evaluation and treatment.

Symptoms

Under the best of circumstances, UI is difficult to categorize based on symptoms alone (Table 105-2). In a study of patients who have SUI based on symptoms and patient history, urodynamics showed that only 72% of patients had SUI as the sole cause of incontinence.[18]

CLINICAL PRESENTATION: Stress Urinary Incontinence

General

- The patient usually notes UI during activities such as exercise, running, lifting, coughing, and sneezing. Occurs much more commonly in women (generally seen only in men with prior lower urinary tract surgery, neurologic disease, or other injury compromising the sphincter).

Symptoms

- Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (minimal or no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

Diagnostic Tests

- Observation of urethral meatus while patient coughs or strains (cough stress test).

TABLE 105-2

Differentiating Bladder Overactivity–Related UI (Urgency Urinary Incontinence) from Urethral Underactivity–Related UI (Stress Urinary Incontinence)

Symptoms	Bladder Overactivity (UUI)	Urethral Underactivity (SUI)
Urgency (strong, sudden desire to void)	Yes	Not common
Frequency with urgency	Yes	Rarely
Leaking during physical activity (eg, coughing, sneezing, lifting)	No	Yes
Amount of urinary leakage with each episode of incontinence	Large if present	Usually small
Ability to reach the toilet in time following an urge to void	No or just barely	Yes
Nocturnal incontinence (presence of wet pads or undergarments in bed)	Yes	Rare
Nocturia (waking to pass urine at night)	Usually	Seldom

SUI, stress urinary incontinence; UUI, urgency urinary incontinence.

Patients with SUI characteristically complain of urinary leakage with physical activity. Volume of leakage is proportional to the level of activity. They will often leak urine during periods of exercise, coughing, sneezing, lifting, or even when rising from a seated to a standing position. Patients with pure SUI will not have leakage when physically inactive, especially when they are supine. Often they will have little or no UI at night, will not awaken to void during the night (nocturia), will not wet the bed, and often do not even wear absorbent products during the night. Urinary urgency and frequency may be associated with SUI, either as a separate component caused by bladder overactivity (mixed incontinence) or as a compensatory mechanism wherein the patient with SUI learns to toilet frequently to prevent large-volume urine loss during physical activity.

Typical symptoms of UUI and bladder overactivity include frequency, urgency, and high-volume incontinence. Nocturia and nocturnal incontinence are often present. Urine leakage is unpredictable, and the volume loss may be quite large. Patients often wear protection both day and night. Urinary frequency can be affected by a number of factors unrelated to bladder overactivity, including excessive fluid intake (polydipsia) and bladder hypersensitivity states such as interstitial cystitis and urinary tract infection. In some patients, bladder overactivity manifests as UI without awareness in the absence of a sense of urinary urgency or frequency. *Urinary urgency*, a sensation of impending micturition, requires intact sensory input from the lower urinary tract. In patients with spinal cord injury, sensory neuropathies, and other neurologic diseases, a diminished ability to perceive or process sensory input from the lower urinary tract may result in bladder overactivity and UI without urgency or urinary frequency. When bladder contraction occurs without warning and sensation is absent, the condition is referred to as *reflex incontinence*.

Patients with overflow incontinence may present with lower abdominal fullness as well as considerable obstructive urinary symptoms, including hesitancy, straining to void, decreased force of urinary stream, interrupted stream, and a vague sense of incomplete bladder emptying. These patients may also have a significant component of urinary frequency and urgency. In patients with acute urinary retention and overflow incontinence, lower abdominal pain may be present. Although these symptoms are not specific for overflow incontinence, they may warrant further investigation, including an assessment of postvoid residual urine volume.

Signs

A presenting complaint of UI mandates a directed physical examination and a brief neurologic assessment. The workup ideally includes an abdominal examination to exclude a distended bladder, neurologic assessment of the perineum and lower extremities, pelvic examination in women (looking especially for evidence of prolapse or hormonal deficiency), and genital and prostate examination in men. Perineal skin maceration, erythema, breakdown, and ulceration may be indicative of chronic, severe UI. Patients with chronic incontinence, especially those who are obese, may also manifest fungal infections of the skin of the perineum and upper thighs.

SUI can usually be objectively demonstrated by having the patient cough or strain during the examination and observing the urethral meatus for a sudden spurt of urine (cough stress test). In women, SUI may be associated with varying degrees of vaginal prolapse, including cystourethrocele (bladder and urethral prolapse).

In both men and women, digital rectal examination provides an opportunity to assess neurological integrity by checking ambient rectal tone, perianal sensation, and the integrity of the sacral reflex arc (eg, anal wink) as well as assess the patient’s ability to perform a voluntary pelvic floor muscle contraction (ie, Kegel exercise), which may be an important factor in deciding on appropriate therapy. In men, a digital examination of the prostate assesses for the presence of prostate cancer, inflammation, and BPH.

A targeted neurologic examination includes assessment of reflexes, rectal tone, and sensory or motor deficits in the lower extremities, which might be indicative of systemic or localized neurologic disease. Neurologic diseases have the potential to affect bladder and sphincter function and thus may have significant implications in the incontinent patient.

CLINICAL PRESENTATION: Urgency Urinary Incontinence

General

- Can have bladder overactivity and UI without urgency if sensory input from the lower urinary tract is absent.

Symptoms

- Urinary frequency (>8 micturitions per day), urgency with or without UI; nocturia (≥1 micturition per night) and enuresis may be present.

Diagnostic Tests

- Urodynamic studies are the gold standard for diagnosis for the diagnosis of detrusor overactivity when the finding of involuntary bladder contractions on the study reproduces the patient’s symptoms. Urinalysis and urine culture should be negative (rule out urinary tract infection as the cause of frequency).

CLINICAL PRESENTATION: Overflow Incontinence (Chronic Urinary Retention)

General

- Important but uncommon type of UI in both men and women. Urethral overactivity is usually due to prostatic enlargement (men) or cystocele formation or surgical overcorrection following stress incontinence surgery in women. Bladder underactivity resulting in overflow incontinence can result from many causes including neurogenic disease, diabetes, and postoperatively from pelvic surgery (eg, radical hysterectomy).

Symptoms

- Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency. Abdominal pain if acute urinary retention is present.

Signs

- Increased postvoid residual urine volume.

Diagnostic Tests

- Assessment of postvoid residual urine either by imaging (ultrasound, etc) or catheterization. Renal function tests to rule out renal failure due to chronic urinary retention.

Prior Medical or Surgical Illness

UI may present in the setting of concurrent, seemingly unrelated illnesses. New-onset UI may be the initial manifestation of systemic illnesses such as diabetes mellitus, metastatic malignancies, and neurologic diseases such as Parkinson's disease, brain tumors, and multiple sclerosis. Central nervous system (CNS) disease, or injury above the level of the pons, generally results in symptoms of bladder overactivity and UUI. Spinal cord injury or disease may manifest as bladder overactivity and UUI or as overflow incontinence, depending on the spinal level and completeness of the injury or disease.

Medications may have wide-ranging effects on lower urinary tract function (see Table 105-1). A thorough inquiry into the use of new medications in the setting of recent-onset UI may show a relationship. **Acute UI manifesting in the immediate postoperative setting may be secondary to a number of factors, including surgical manipulation and immobility, and to a number of medications, especially opioid analgesics and sedative-hypnotics.**

Prior surgery may have effects on lower urinary tract function. UI following prostate surgery in men is highly suggestive of injury to the sphincter and resultant SUI. Pelvic surgery for benign and malignant conditions may result in denervation or injury to the lower urinary tract. This includes bowel surgery and gynecologic procedures. For example, new-onset total UI following gynecologic surgery suggests intraoperative urinary tract injury and subsequent development of a postoperative genitourinary fistula. Radiation therapy to the pelvis for malignant disease (eg, prostate cancer or cervical cancer) may result in injury to the bladder or urethra and subsequent UI.

In women, UI may be related to several gynecologic factors including childbirth, hormonal status, and prior gynecologic surgery, although the relationship of some of these factors to UI has come under debate.[19] Pregnancy and childbirth, particularly vaginal delivery, are associated with SUI and pelvic prolapse. Significant SUI in the nulliparous woman is uncommon. UI that becomes progressive at or around menopause suggests a hormonal component that may be responsive to estrogen or hormone replacement therapy.

UI may present in the setting of other significant pelvic floor disorders, signs, and symptoms. Constipation, diarrhea, fecal incontinence, dyspareunia, sexual dysfunction, and pelvic pain may be related to UI. A history of gross hematuria in the setting of UI mandates further urologic investigation, including radiologic imaging of the upper urinary tract and cystoscopy. Acute dysuria with or without hematuria in the setting of UI suggests cystitis. Urinalysis and urine culture should be performed in these patients.

TREATMENT

Desired Outcomes

③The efficacy goals for the management of UI include restoration of continence, reduction of the number of UI episodes, and prevention of complications (perineal dermatitis, pressure ulcers, falls, etc.). Other desired outcomes are minimization of adverse treatment consequences and cost, improvement in the patient's quality of life, lesser care burden, and reduced risk of nursing home placement.

General Approach to Treatment

Nonsurgical, nonpharmacologic intervention is the first-line treatment for UI. Drug therapy may be considered in patients whose UI is not adequately controlled by nonpharmacologic therapies and in those who have no major contraindications to drug treatment. In general, pharmacotherapy provides a better response when combined with behavioral interventions.[20] Selection of agent should be based on the type of UI, and patient characteristics (eg, age, comorbidities, concurrent drug therapies, ability to maintain medication adherence). Surgery can be considered when the degree of bother or lifestyle compromise is sufficient and other nonsurgical interventions are undesired or ineffective.

Antimuscarinic agents have been the mainstay of pharmacotherapy for OAB and UUI. According to the American Urological Association (AUA) guideline,[21] clinicians should avoid antimuscarinic agents in patients with narrow-angle glaucoma unless approved by the treating ophthalmologist. Antimuscarinic agents should be cautiously used in patients with frailty, impaired gastric emptying, or a history of urinary retention, or in those who are taking other drugs with anticholinergic properties. When one agent offers inadequate symptom control and/or unacceptable adverse drug events, consider a dose modification or switching to another agent. Before initiating antimuscarinic therapy, patients should be informed of adverse effects and strategies to minimize them. Before abandoning effective antimuscarinic therapy, clinicians should manage constipation and dry mouth (bowel regimen, fluid management, dose modification, or alternative antimuscarinics).[21] β_3-Agonists are newer drug alternatives for UUI.

Nonpharmacologic Nonsurgical Treatment

④Nonpharmacologic, nonsurgical treatment of UI is recommended as the first-line treatment at a primary care level. It is the only option for patients in whom pharmacologic and/or surgical management is inappropriate or undesired. Examples of patients who fulfill these criteria for nonpharmacologic treatment include those with mild-to-moderate symptoms and who do not want to take medication; those with comorbid conditions that place them at high risk for adverse effects from drug therapy; those who are not medically fit for surgery; those who plan future pregnancies (which may adversely affect long-term surgical outcomes); those with overflow incontinence whose condition is not amenable to surgery or drug therapy; and those who are delaying surgery or do not want to undergo surgery.[22]

Nondrug interventions for UI include behavioral interventions, external neuromodulation, anti-incontinence devices, and supportive interventions (Table 105-3).[21] Behavioral interventions are generally the first-line treatment for SUI, UUI, and mixed UI. Interventions include lifestyle modifications, voiding schedule regimens, and pelvic floor muscle rehabilitation based on the patient's treatment preferences. Notably, both stress and urgency urinary incontinence are associated with obesity. Several studies have demonstrated that weight loss benefits patients with UI.[23] Because the key to success with any type of behavioral intervention is motivation of patients or caregivers, these individuals must be active participants in developing a treatment plan. Regular follow-up is needed to help motivate patients and caregivers, provide reassurance and support, and monitor treatment outcomes. Patients should be informed that it takes 8 to 12 weeks for behavioral interventions to be effective.

TABLE 105-3

Nonpharmacologic Management of Urinary Incontinence

Intervention	Description	Patient Characteristics
Lifestyle Modifications		
Behavioral changes (eg, fluid and caffeine	Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate UI	Used as first-line therapies or in combination with pharmacological treatment in patients with stress, urgency, and mixed incontinence

modifications, smoking cessation, weight loss, constipation prevention)		
Scheduling Regimens		
Timed voiding	Toileting on a fixed schedule where interval does not change, typically every 2 hours during waking hours	Used for patients with cognitive or physical impairments causing disability-associated incontinence
Habit training	Scheduled toiletings with adjustments of voiding intervals (longer or shorter) based on patient's voiding pattern	Used for institutionalized or homebound patients with cognitive or physical impairments
Prompted voiding	Scheduled toiletings that require prompts to void from a caregiver, typically every 2 hours; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting	Used for patients who are functionally able to use toilet or toilet substitute, able to feel urge sensation, and able to request toileting assistance appropriately; primarily used in institutional settings or in homebound patients with an available caregiver
Bladder training	Scheduled toiletings with progressive voiding intervals; includes teaching urgency suppression strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy	Used for stress, urgency, and mixed incontinence in patients who are cognitively intact, able to toilet, and motivated to comply with training program
Pelvic Floor Muscle Rehabilitation		
Pelvic floor muscle exercises (eg, Kegel exercises)	Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for prevention of stress leakage and urge inhibition	Used for stress, urgency, and mixed incontinence in patients who can isolate and correctly contract pelvic floor muscles; requires cognitively intact and highly motivated patient
Biofeedback	Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction or urge inhibition; home trainers available	Used for stress, urgency, and mixed incontinence in patients who have the capability to learn voluntary control through observation and are motivated; used in conjunction with pelvic floor muscle exercises
Vaginal weight training	Active retention of increasing vaginal weights; typically used in combination with pelvic floor muscle exercises at least twice per day	Women with stress incontinence who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and have sufficient vaginal vault and introitus to retain cone, and are highly motivated; contraindicated in patients with moderate-to-severe pelvic organ prolapse
External Neuromodulation		
Nonimplantable electrical stimulation	Application of electrical current through vaginal, anal, surface, or fine needle electrodes; used to inhibit bladder overactivity and improve awareness,	Used for stress, urgency, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception; urinary retention, history of cardiac arrhythmia, cardiac

	contractility, and efficacy of pelvic floor muscle contraction; handheld stimulators for home use are available	pacemakers, implantable defibrillators, pregnant or attempting pregnancy; vaginal or anal electrodes are contraindicated in moderate or severe pelvic organ prolapse
Percutaneous tibial nerve stimulation	Application of a pulsed electrical current through a fine needle electrode placed externally near the tibial nerve	Used for treatment of overactive bladder with urinary urgency, frequency, and urgency incontinence; contraindicated in patients with pacemakers or implantable defibrillators, prone to excessive bleeding, or women who are pregnant
Extracorporeal magnetic electrical stimulation	Pulsed magnetic stimulation to pelvic floor musculature causing depolarization of motor neurons, thus inducing pelvic floor muscle contraction; stimulation is provided through a specially designed chair that contains a device for producing a pulsing magnetic field	Used for treatment of stress, urgency, and mixed incontinence; contraindicated in patients with demand cardiac pacemakers or metallic joint replacements; may be useful treatment option when other approaches fail or are not feasible
Alternative Medicine Therapies		
Acupuncture	Involves insertion of disposable sterile fine stainless steel needles into points on the skin that are thought to suppress or stimulate spinal and/or supraspinal reflexes to the bladder and/or urethra	Used for stress, urgency, and mixed incontinence and UI due to spinal cord injury
Anti-Incontinence Devices		
Bed or pant alarms	Sensor devices that respond to wetness; used to awaken or alert individuals via noise or vibrating mechanism	Primarily used for nocturnal enuresis in children; system available for monitoring incontinence in home care and institutional environments
Pessaries	Intravaginal devices designed to support the bladder neck, relieve minor-to-moderate pelvic organ prolapse, and change pressure transmission to the urethra	Used for female stress incontinence and mild-to-moderate pelvic organ prolapse; in postmenopausal women, topical estrogen therapy is typically prescribed to prevent ulceration and breakdown of vaginal tissue; requires good manual dexterity to manipulate device
Urethral insert (women only)	Intraurethral device	Used in female stress incontinence with stress incontinence who are cognitively intact and have good manual dexterity
Urethral compression device (men only)	Penile clamp	Used in men patients with stress incontinence who are cognitively intact and have good manual dexterity
External collection devices (men only)	Condom catheter with leg bag	Used in men with urgency, stress, and overflow incontinence and in those with functional impairments
External urine collection devices for women	Female external catheter with suction wicking system that pulls urine through collector tubing into collection canister	Used in women with incontinence related to functional impairments in rehabilitation and hospital settings
Catheters	Disposable, intermittent urethral catheters and indwelling urethral and suprapubic catheters	Used for overflow incontinence; used in patients who are bed-bound or with significant mobility impairments and severe incontinence; those

		with terminal illness; those with sacral pressure ulcers until healing occurs
Supportive Interventions		
Toileting substitutes and other environmental modifications	Female and male urinals, bedside commodes, elevated toilet seats, grab bars, and frames	Used for patients with mobility impairments that make reaching toilet in timely fashion difficult
Absorbent products	Variety of reusable and disposable liners, pads, male drip collectors, male guard, collector undergarment, fitted brief, and pant systems; some products contain a polymer that absorb and wick urine away from the body	Used for all types of incontinence
Physical therapy	Gait and/or strength training	Used for older patients with mobility impairments that make reaching a toilet in timely fashion difficult

External neuromodulation may include nonimplantable electrical stimulation (EStim), percutaneous tibial nerve stimulation (PTNS), or extracorporeal magnetic stimulation (MStim). Electrical stimulation is typically prescribed when traditional pelvic floor muscle rehabilitation has failed. Anti-incontinence devices such as bed alarms, catheters, pessaries, penile clamps, and external collection devices are reserved for special situations depending on patients' UI symptoms, cognitive and mobility status, and overall health status. Supportive interventions such as physical therapy may be beneficial for patients with muscle weakness and slow gait to reach the toilet in a timelier manner, and absorbent products will provide greater confidence in dealing with unpredictable urine loss. Penile clamps and external collection devices are available for men and women with significant functional impairment.

Surgical Treatment

Only rarely does surgery play a role in the initial management of UI. In the absence of secondary complications from UI (eg, skin breakdown or infection), the decision to surgically treat symptomatic UI should be based on the premise that the degree of bother or lifestyle compromise to the patient is great enough to warrant an elective operation, and that nonsurgical therapy either is undesired or has been ineffective.

Successful application of surgery depends mostly on defining the underlying abnormalities responsible for UI (bladder vs urethra, underactivity vs overactivity). Once the underlying factors are determined, other considerations include renal function, sexual function, severity of leakage, history of abdominal or pelvic surgery, presence of concurrent abdominal or pelvic pathology requiring surgical correction, and finally the patient's suitability for the procedure and willingness to accept the risks of surgery.

If patients with uncomplicated SUI become dissatisfied with the initial management approaches of pelvic floor exercises, medications, and/or behavioral modification, surgical treatment assumes the primary role. Surgical correction of female SUI (urethral underactivity) is directed toward either (a) repositioning the urethra and/or creating a backboard of support, or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic (intra-abdominal) position that is receptive to changes in intra-abdominal pressure; or (b) improving the sealing mechanism and/or creating compression or otherwise augmenting the urethral resistance provided by the intrinsic sphincteric unit, with (ie, sling) or without (ie, periurethral injectable bulking agents) urethral and bladder neck support.

Bulking agents are injected into the urethra at the level of the urinary sphincter as an office-based procedure and are generally considered quite safe. However, their durability and efficacy are likely inferior to other options.[24]

Midurethral synthetic slings have become the most common approach to the treatment of SUI in women in the United States. These can be inserted as outpatient procedures that have shorter convalescence periods and allow faster return to usual activities compared with many of the older procedures. These procedures are generally felt to be highly durable and efficacious. However, safety concerns have been expressed regarding the implantation of surgical mesh in some patients, the implications of which are yet to be fully clarified.[25]

SUI in men is rare in the absence of prior pelvic surgery, injury, or neurologic disease. When it occurs, SUI in men can be treated in a number of ways.[26] Bulking agents can be injected periurethrally and submucosally into the region of the external urinary sphincter but have fallen out of favor due to poor short- and long-term outcomes. This approach is less effective and far less durable than alternative surgical procedures, although it can be performed in the office setting without the need for general anesthesia. The artificial urinary sphincter is generally considered to be the gold standard for treatment of male SUI.[27] Placement of this manually operated silicone device has been associated with high long-term success and satisfaction rates.[27] Male slings and external urethral compression devices placed through a perineal incision are alternatives to the artificial urinary sphincter in some individuals with mild-to-moderate SUI.[28] However, long-term efficacy and safety data on large numbers of patients is lacking.[29]

Most patients with UUI are managed nonsurgically with a combination of behavioral modification, pelvic floor exercises, and pharmacologic therapy. However, for patients refractory to such measures, invasive therapy can be beneficial. Posterior tibial nerve stimulation is an office-based percutaneous treatment for UUI or OAB. Therapy consists of weekly 30-minute treatments with a needle placed posteriorly to the medial malleolus of the ankle for 3 months.[30] Efficacy is similar to or slightly better than oral pharmacotherapy. However, long-term efficacy and safety data are lacking.

Surgery for the treatment of UUI generally consists of implantation of a sacral nerve stimulator (neuromodulation) or endoscopic office-based injection of botulinum toxin directly into the detrusor muscle.[31,32] Neuromodulation is a staged surgical procedure in which a neurostimulator lead is placed transforaminally at the level of sacral spinal cord root S3. Its exact mechanism is unknown, but the device may exert its favorable effects on urination and UUI by rebalancing the afferent and efferent nerve impulses to the lower urinary tract and pelvic floor. The injection of botulinum toxin is performed in the office generally with local anesthesia. Following transurethral injection directly into the detrusor muscle using a small needle in a template fashion, the toxin is taken up by the local neurons. The intracellular toxin cleaves SNAP-25, a cystoplasmic protein critical for the attachment of neurotransmitter containing vesicles to the cell membrane at the nerve terminal. As the vesicles containing neurotransmitter are unable to fuse to the cell membrane and release its contents into the synaptic cleft, neural transmission to the postsynaptic muscle fascicle is interrupted. This results in a graded, initially irreversible but transient weakness and paralysis of the affected muscle. The duration of effect of the toxin is about 4 to 8 months, after which repeat injection is necessary to maintain effect. The therapeutic algorithm involving these two choices for treatment of refractory UUI is evolving, and is determined largely by patient preference.[33]

Few surgical treatments for bladder underactivity are effective. After an appropriate evaluation for reversible causes, the most effective management of this condition is intermittent self-catheterization performed by the patient or a caregiver three or four times per day. Sacral nerve stimulation (neuromodulation) has shown some efficacy in this patient population, but success rates for detrusor underactivity (nonobstructive urinary retention) are inferior to that seen for the indication of urgency UI with urinary frequency and urgency.[34] Proper patient selection for this therapy remains poorly defined. Alternative methods of management that are less satisfactory or more invasive include indwelling urethral or suprapubic catheters and urinary diversion.

Urethral overactivity is most commonly caused by anatomic obstruction. Anatomic obstruction in men is most often caused by benign prostatic enlargement. Treatments may include transurethral surgical resection of the prostate (see Chapter 104, “Benign Prostatic Hyperplasia”). Rarely, bladder outlet obstruction is caused by a functional obstruction at the level of the bladder neck or external sphincter. Hypertrophy of the smooth muscle fibers at the level of the bladder neck in men and women may result in obstruction to the flow of urine. In patients who do not respond to pharmacologic therapy with α-adrenergic receptor antagonists, endoscopic incision using the cystoscope (resectoscope) is highly effective in treating this uncommon condition.

Pharmacologic Therapy

Urgency Urinary Incontinence

⑤ Antimuscarinic agents and β_3-adrenergic agonists are the second-line drug treatments for urgency UI. Table 105-4 summarizes AUA recommendations for treating OAB in adults.[21] Table 105-5 lists the usual dosage for approved agents for OAB or UUI. Table 105-6 suggests common monitoring parameters for these agents.

TABLE 105-4

AUA Guideline for Treatment of Overactive Bladder in Adults

Recommendation	Evidence Strength Grade[a]
First-Line Treatments	
Behavioral therapies (eg, bladder training, bladder control strategies, pelvic floor muscle training, fluid management)	B
Behavioral therapies may be combined with pharmacologic therapies	C
Second-Line Treatments	
Oral antimuscarinics or β_3-adrenergic agonist as second-line therapy	B
If an IR and an ER formulation are available, prefer ER formulations because of lower rates of dry mouth	B
Transdermal oxybutynin (patch or gel) may be offered	C
Combination therapy with an oral antimuscarinic and a β_3-adrenergic agonist is acceptable for patients refractory to monotherapy with either class of drug	C
Third-Line Treatments	
Intradetrusor onabotulinum toxin A (100 units) in carefully selected patients who have been refractory to first- and second-line OAB treatments[b]	B
Peripheral tibial nerve stimulation in a carefully selected patient population	C
Sacral neuromodulation in carefully selected patients with severe refractory OAB symptoms or in those who are not candidates for second-line therapy and are willing to undergo a surgical procedure	C

AUA, American Urological Association; ER, extended-release; IR, immediate-release; OAB, overactive bladder.

[a] When sufficient evidence existed, the body of evidence for a particular treatment was assigned a strength rating of A (high), B (moderate), or C (low). Both B and C indicate that benefits outweigh risks/burdens.

[b] The patient must be able and willing to return for frequent postvoid residual evaluation and able and willing to perform self-catheterization if necessary.

TABLE 105-5

Dosing of Medications Approved for OAB or UUI

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Anticholinergics/Antimuscarinics					

Oxybutynin IR	Ditropan	2.5 mg twice daily	2.5-5 mg two to four times daily		Titrate in increments of 2.5 mg/day every 1-2 months; available in oral solution
Oxybutynin XL	Ditropan XL	5-10 mg once daily	5-30 mg once daily		Adjust dose in 5-mg increments at weekly interval; swallow whole
Oxybutynin TDS	Oxytrol Oxytrol for Women (OTC)		3.9 mg/day apply one patch twice weekly		Apply every 3-4 days; rotate application site
Oxybutynin gel 10%	Gelnique		One sachet (100 mg) topically daily		Apply to clean and dry, intact skin on abdomen, thighs or upper arms/shoulders; contains alcohol
Oxybutynin gel 3%	Gelnique 3%		Three pumps (84 mg) topically daily		Same as above
Tolterodine IR	Detrol		1-2 mg twice daily	1 mg twice daily if patient is taking CYP3A4 inhibitors, or with renal/hepatic impairment	Avoid in patients with creatinine clearance less than 10 mL/min (0.17 mL/s) or severe hepatic impairment
Tolterodine LA	Detrol LA		2-4 mg once daily	2 mg once daily in those who are taking CYP3A4 inhibitors (ketoconazole, itraconazole, clarithromycin, or ritonavir), with hepatic impairment (Child-Pugh class A or B), or severe renal impairment [creatinine clearance 10 to 30 mL/min (0.17-0.50 mL/s)]	Swallow whole; avoid in patients with creatinine clearance ≤10 mL/min (0.17 mL/s) or severe hepatic impairment
Trospium chloride IR	Sanctura		20 mg twice daily	20 mg once daily in patient age ≥75 years or creatinine clearance ≤30 mL/min (0.5 mL/s)	Take 1 hour before meals or on empty stomach; patient age ≥75 years should take at bedtime
Trospium chloride ER	Sanctura XR		60 mg once daily	Avoid in patient age ≥75 years or creatinine clearance ≤30 mL/min (0.5 mL/s)	Take 1 hour before meals or on empty stomach; swallow whole
Solifenacin	VESIcare	5 mg	5-10 mg	5 mg daily if patient is taking CYP3A4 inhibitors or with creatinine	Swallow whole

		daily	once daily	clearance ≤30 mL/min (0.5 mL/s) or moderate hepatic impairment; avoid in severe hepatic impairment	
			Pediatric: use suspension dosed based on body weight		
Darifenacin ER	Enablex	7.5 mg once daily	7.5-15 mg once daily	7.5 mg daily if patient is taking potent CYP3A4 inhibitors or with moderate hepatic impairment; avoid in severe hepatic impairment	Titrate dose after at least 2 weeks; swallow whole
Fesoterodine ER	Toviaz	4 mg once daily	4-8 mg once daily	4 mg daily if patient is taking potent CYP3A4 inhibitors or with creatinine clearance ≤30 mL/min (0.5 mL/s); avoid in severe hepatic impairment	Prodrug (metabolized to 5-hydroxymethyl tolterodine); swallow whole
β_3-Adrenergic Agonist					
Mirabegron ER	Myrbetriq	25 mg once daily	25-50 mg once daily	25 mg once daily if creatinine clearance 15-29 mL/min (0.25-0.49 mL/s) or moderate hepatic impairment; avoid in patients with ESRD or severe hepatic impairment	Swallow whole
Vibegron	Gemtase	75 mg once daily		Avoid in patients with end-stage kidney disease with or without hemodialysis, or severe hepatic impairment	Swallow whole. Tablets may be crushed and mixed with applesauce

CYP, cytochrome P450 enzyme; ER, extended-release; ESRD, end-stage renal disease; IR, immediate release; LA, long acting; OAB, overactive bladder; OTC, over-the-counter; TDS, transdermal system; UUI, urge urinary incontinence; XL, extended release.

TABLE 105-6

Monitoring of Medications Approved for OAB or UUI

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Antimuscarinic			
Oxybutynin IR Oxybutynin XL Oxybutynin TDS Oxybutynin gel 10% Oxybutynin gel 3% Tolterodine IR Tolterodine LA Trospium chloride IR Trospium chloride ER Solifenacin Darifenacin ER Fesoterodine ER	Anticholinergic adverse effects: dry mouth, constipation, headache, dyspepsia, dry eyes, blurred vision, cognitive impairment, tachycardia, sedation, orthostatic hypotension Application site reactions (topical agents): pruritus, erythema	Contraindications and precautions: urinary retention, gastric retention, severely decreased GI motility, angioedema, myasthenia gravis, uncontrolled narrow-angle glaucoma Worsening of renal/hepatic condition or concomitant drug therapy, which may necessitate dosage reduction or drug cessation Mental status change or risk for falls in elderly or frail patients	In general, ER, LA, XL, and topical products are associated with fewer anticholinergic adverse effects, particularly dry mouth Possible transference of drug from topical application Avoid open fire or smoke until alcohol-based gel has dried
β_3-Adrenergic Agonist			
Mirabegron ER	Hypertension, nasopharyngitis, urinary tract infection, headache	Precautions: urinary retention, severe uncontrolled hypertension Worsening of renal/hepatic condition, which may necessitate dosage reduction or drug cessation Increased effect of narrow therapeutic index drugs that are CYP2D6 substrates QT prolongation	Mirabegron is a CYP2D6 inhibitor; may increase digoxin level
Vibegron	Headache, nasopharyngitis, hot flashes, gastrointestinal symptoms, upper respiratory tract infection	Precautions: bladder flow obstruction, hepatic/renal impairment	Minor substrate of CYP3A4, P-glycoprotein/ABCB1; may increase digoxin level

CYP, cytochrome P450 enzyme; ER, extended-release; IR, immediate release; LA, long acting; OAB, overactive bladder; TDS, transdermal system; UUI, urge urinary incontinence; XL, extended release.

Antimuscarinic agents (see Table 105-5) antagonize muscarinic receptors and suppress premature detrusor contractions, thereby enhance bladder storage. They have similar contraindications, precautions, and side-effect profiles, with incidence/severity varies with each individual agent.[35] These agents improve quality of life, and are considered equally effective based on clinical efficacy in reducing UI episodes, decreasing micturitions per day, and increasing urine volume voided per micturition.[36] Antimuscarinic agents may worsen cognitive function, especially in older adults. Also, they may antagonize the therapeutic effects of acetylcholine esterase inhibitors indicated for dementia.

Oxybutynin

Oxybutynin immediate release (IR) is the oldest and least expensive treatment for UUI. It gives substantial nonurinary antimuscarinic effects, including orthostatic hypotension, sedation, and weight gain (see Table 105-6).[37] These adverse effects may jeopardize medication adherence and prevent dose escalation. Its multiple daily dosing may be too complicated for patients with cognitive impairment or those who are taking multiple medications. Consider dose reduction if side effects become bothersome. Use sugarless gum, hard candy, or a saliva substitute for dry mouth and increase fluid/fiber intake, physical activity, and/or laxative therapy for constipation.

An extended-release (XL) formulation of oxybutynin is an alternative therapy in patients who cannot tolerate IR formulation. It delivers a controlled amount of oxybutynin over a 24-hour period, and has a reduced first-pass metabolism. It gives a lower concentration of active metabolite, *N*-desethyloxybutynin, which is associated with dry mouth as a side effect.[38] In short-term studies, oxybutynin XL was better tolerated than oxybutynin IR, and at least as effective as tolterodine IR or long acting (LA) in managing urinary symptoms.[38] Drug interactions may occur when oxybutynin is used with other anticholinergic drugs, potent CYP3A4 inhibitors (eg, itraconazole, miconazole, erythromycin, and clarithromycin), and acetylcholinesterase inhibitors.[38]

Nonoral formulations of oxybutynin are available for better tolerability. The oxybutynin transdermal system (TDS) is the first OTC treatment for OAB in women aged 18 years or older. It has a similar efficacy as oxybutynin IR or tolterodine LA.[39,40] It bypasses first-pass hepatic and gut metabolism and is more tolerable (anticholinergic side effects <10%).[39] It has been associated with improved quality of life and work productivity. Patients should apply oxybutynin TDS to dry, intact skin on the abdomen, hip, or buttocks every 3 to 4 days (twice weekly). Rotating application site at least weekly helps to minimize local reactions: pruritus (14%-17%) and erythema (6%-9%).[39]

Oxybutynin topical gel causes less dry mouth than oral oxybutynin (6.1% vs 73.1%).[41–43] In older patients with frailty, long-term use warrants proper monitoring for cognitive impairment and anticholinergic effects.[44] Patients should not apply sunscreen within 30 minutes before or after application or shower within 1 hour after application. They should also avoid the transfer of gel to others via vigorous skin contact at the application site; avoid open fires or exposure to smoking until the alcohol-based gel has dried.[41,42]

Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist that is as effective as oxybutynin IR, but gives better tolerability and thus medication adherence.[45] Tolterodine is predominantly eliminated by hepatic metabolism, which is partially under the control of genetic polymorphism.[46] The principal metabolic pathway in extensive metabolizers involves oxidation of the parent drug by CYP isoenzyme 2D6 to the active 5-hydroxymethyl metabolite (DD01). In CYP2D6 poor metabolizers (approximately 7% of the US population), the principal metabolic pathway involves CYP3A4. Because tolterodine is principally metabolized by CYP3A4 in this case, monitor for impaired drug limitation when given concomitantly with CYP3A4 inhibitors (eg, fluoxetine, sertraline, fluvoxamine, macrolide antibiotics, azole antifungals, and grapefruit juice). Concurrent use of fluoxetine, a dual inhibitor of CYP2D6 and 3A4 can significantly increase tolterodine level.[46] Caution is also advised with individuals who carry nonfunctional CYP2D6*13 allele.[46,47] The maximum benefit from tolterodine may take up to 8 weeks after therapy initiation or dose escalation.[46] The most common adverse effects of tolterodine are dry mouth, dyspepsia, headache, constipation, and dry eyes. Of note, patients who have known hypersensitivity to fesoterodine fumarate should not receive tolterodine because both agents are metabolized to DD01. Monitor for QT prolongation with concomitant use of Class IA (eg, quinidine, procainamide) or Class III (eg, amiodarone, sotalol) antiarrhythmic medications.[47]

Tolterodine long acting (LA) offers a convenient once-daily dosing and causes less dry mouth than IR formulation.[48] It also improves OAB symptoms in men who were taking α-adrenergic blockers.[49] It may take up to 8 weeks to see maximum benefit after starting therapy or dose escalation.[48]

Fesoterodine Fumarate

Fesoterodine fumarate is also indicated for symptoms of urinary frequency, urgency, or urgency incontinence. It is a prodrug that is metabolized to its active metabolite, 5-hydroxymethyl tolterodine (also a metabolite of tolterodine), by nonspecific plasma esterases.[50] In a short-term study, fesoterodine was better than tolterodine ER 4 mg and placebo on reducing UUI episodes, micturitions, urgency, and improving health-related quality of life. However, fesoterodine caused more dry mouth (28% vs 13%) and constipation (4% vs 3%).

More patients discontinued fesoterodine therapy due to adverse events (5% vs 3%).[51] The most common adverse effects of fesoterodine are dose-related dry mouth (27%), constipation (5.1%), dyspepsia (2%), and dry eyes (1.6%).[50] The most common adverse effects of fesoterodine are dose-related dry mouth (27%), constipation (5.1%), dyspepsia (2%), and dry eyes (1.6%).

Trospium Chloride

Trospium chloride, a quaternary ammonium anticholinergic, is a second-generation antimuscarinic agent for urgency UI. Trospium chloride is poorly absorbed after oral administration (<10%), and food reduces bioavailability by 70% to 80%. It is principally cleared by the renal route (60%). Metabolites account for approximately 40% of the excreted dose following oral administration. The major metabolic pathway is hypothesized as ester hydrolysis with subsequent conjugation. CYP is not expected to contribute significantly to the elimination of trospium. The plasma half-life is approximately 20 hours; with renal clearance about 30 L/hr. Active tubular secretion is a major route of elimination for trospium. When creatinine clearance is less than 30 mL/min (0.50 mL/s), drug exposure and drug concentration are significantly increased.[45]

Trospium chloride IR was noninferior to oxybutynin IR, but was associated with less dry mouth.[52] Anticholinergic side effects occur more often in patients aged 75 years and older due to pharmacodynamics changes (ie, increased sensitivity). Trospium may interact with other drugs that are eliminated by active tubular secretion via competition (eg, procainamide, pancuronium, morphine, vancomycin, and tenofovir).[45] Trospium chloride extended-release offers once-daily dosing with established efficacy and safety in patients with OAB.[53] Trospium is eliminated primarily unchanged in the urine; thus it is not recommended in patients with severe renal impairment It interacts with alcohol (increased drowsiness), antacid (increase or decrease trospium exposure), and metformin (reduced trospium level by 34%).[54] It must be taken on an empty stomach (1 hour before or 2 hours after meals) as food decreases the bioavailability by up to 60%.[53] Common adverse effects with trospium chloride ER are dry mouth (11%), constipation (9%), dizziness (2%), dry eyes (1.6%), flatulence (1.6%), nausea (1.4%), and abdominal pain (1.4%).[54]

Solifenacin Succinate

Solifenacin succinate is a second-generation antimuscarinic agent indicated for the treatment of OAB with urgency incontinence, urgency, and urinary frequency.[55] It is also indicated for neurogenic detrusor overactivity in children 2 years or older and adolescents.[56] Solifenacin is associated with less dry mouth than oxybutynin IR (35% vs 83%).It is well absorbed (bioavailability 88%) and taken without regard to food. It is principally eliminated via metabolism (CYP3A4) and renal excretion of metabolites It has a terminal disposition half-life of 50 to 60 hours.[55]

The recommended dose of solifenacin is 5 mg once daily with or without food. If the drug is well tolerated, the dose can be increased to 10 mg once daily. See Table 105-6 for dose adjustment based on renal/hepatic impairment and drug interactions. The most common adverse reactions of solifenacin are dry mouth (11%-28%), constipation (5%-13%), urinary tract infection (4%-5%), and blurred vision (3%-5%). It interacts with CYP3A4 inhibitors and inducers; close patient monitoring is required. Prolonged corrected QT intervals have been reported with high-dose solifenacin.[55]

Darifenacin

Darifenacin is another second-generation antimuscarinic for the management of OAB or UUI. It improves urinary symptoms, and quality of life.[57,58] The bioavailability of extended-release (ER) formulation is low (25%), and is affected by CYP2D6 genotype and treatment dose. Darifenacin is extensively metabolized, with cumulative urinary excretion of the parent compound less than 10%. The 2D6 and 3A4 isoenzymes of CYP are responsible for darifenacin metabolism. Thus, pharmacogenomic profile may impact the clinical response to darifenacin.[59] With a mean terminal disposition half-life of 3 to 5 hours (depending on CYP2D6 metabolizer status), an ER formulation is needed to allow once-daily dosing.[60] Darifenacin ER should be initiated at 7.5 mg once daily, and may be increased to 15 mg once daily after 2 weeks to target clinical response. See Table 105-6 for dose adjustment based on renal/hepatic impairment and drug interactions. It must be swallowed whole without chewing, dividing, or crushing. Common adverse reactions are constipation (21%), dry mouth (19%), headache (7%), dyspepsia (5%), and nausea (4%). Darifenacin may interact with substrates of CYP2D6 (flecainide, thioridazine, and tricyclic antidepressants).[60]

Mirabegron

Mirabegron is approved by FDA for the treatment of OAB with symptoms of UUI, urgency, and urinary frequency.

⑥ Mirabegron is another first-line drug treatment for managing UUI. It increases bladder capacity by relaxing the detrusor smooth muscle during the storage phase of the urinary bladder fill-void cycle through the activation of β_3-adrenergic receptors. Similar to antimuscarinic agents, it is modestly effective and reduces urinary frequency and incontinence episodes by less than one per day. It is associated with nonsignificant improvements in UUI, urgency episodes, and quality-of-life measures. It has been shown to have similar efficacy as with tolterodine ER.[21,61] It reduces mean number of incontinence episodes per 24 hours, mean number of micturitions per 24 hours, and increased mean volume voided per micturition. The efficacy is usually seen during 4 to 8 weeks of therapy.[62]

Mirabegron reaches its peak plasma concentrations at approximately 3.5 hours and has an oral bioavailability of 29% to 35%. It achieves steady state within 7 days of therapy. It can be taken with or without food. Mirabegron is extensively distributed in the body, with a volume of distribution of approximately 1,670 L. It has protein binding of approximately 71% to both albumin and α_1-acid glycoprotein. Mirabegron is metabolized via multiple pathways involving dealkylation, oxidation, glucuronidation, and amide hydrolysis. It has two inactive metabolites (16% and 11% of total exposure), respectively. Isoenzymes CYP2D6 and 3A4 play a limited role in its elimination. Poor metabolizers of CYP2D6 had an increased mean peak concentration and drug exposure compared to extensive metabolizers of CYP2D6 (16% and 17%, respectively). Other enzymes that are involved in mirabegron metabolism include butylcholinesterase, uridine diphospho-glucuronosyltransferases (UGT), and possibly alcohol dehydrogenase.

Total body clearance of mirabegron is about 57 L/hr, with a terminal elimination half-life of 50 hours. Renal clearance equals approximately 13 L/hr, primarily through active tubular secretion along with glomerular filtration. The urinary elimination of unchanged mirabegron is dose dependent and ranges from 6% to 12% after a daily dose of 25 to 100 mg.[61]

Mirabegron should be initiated at 25 mg once daily, and may titrate upward to 50 mg once daily after 8 weeks, based on individual efficacy and tolerability; limit dose to 25 mg once daily in patients with severe renal impairment or moderate hepatic disease. Mirabegron is available in ER tablets, and should be swallowed whole with water without chewing, dividing, or crushing. It should be avoided in patients with end-stage renal disease, severe hepatic impairment, or severe uncontrolled hypertension (≥180/110 mm Hg). Most commonly reported adverse reactions were hypertension (7%-11%), nasopharyngitis (4%), urinary tract infection (3%-6%), and headache (3%-4%). Patient should be monitored for increased blood pressure and urinary retention, particularly in patients with bladder outlet obstruction or those who are taking anticholinergic drugs.[62] Mirabegron has similar adverse effects (except less dry mouth) when compared with tolterodine ER. Blood pressure and heart rate changes were minimal (<1 mm Hg and <2 beats/min, respectively).[21] Mirabegron is a moderate inhibitor of CYP2D6, and may affect the dosage requirement for some 2D6 substrates (eg, metoprolol and desipramine). Thus, drug-level monitoring for certain medications with a narrow therapeutic range, such as thioridazine, flecainide, and propafenone, is advised.[61] The efficacy and safety of combination therapy with mirabegron (25 or 50 mg) and solifenacin (5 mg) have been evaluated in clinical trials.[63–65] Combination therapy demonstrated improved efficacy without significant increase in side effects as seen in monotherapy.[21]

Vibegron

Vibegron is approved by FDA for the treatment of OAB with symptoms of UUI, urgency, and urinary frequency in adults.

Like mirabegron, vibegron is a β_3-adrenergic receptor agonist. It activates β_3-adrenergic receptors in the bladder, resulting in relaxation of the detrusor smooth muscle during the urine storage phase, thus increasing bladder capacity. Vibegron reaches its peak plasma concentrations within 1 to 3.5 hours of administration and has a protein binding of 50%. The usual dose is 75 mg once daily with or without food.

Vibegron is extensively distributed in the body, with a volume of distribution of approximately 6,000 L. It is metabolized via minor metabolism hepatically via CYP3A4. It has a terminal elimination half-life of 30 hours and is excreted unchanged in feces (54%) and urine (19%).[66] Other β_3-adrenergic agonists in development include solabegron, ritobegron, and vibegron.[67–69] Table 105-7 lists the frequencies for the most common adverse events for all approved treatment oral agents based on manufacturers' product information.

TABLE 105-7

Adverse Event Incidence Rates (%) with Approved Drugs for Bladder Overactivity[a]

Drug	Dry Mouth	Constipation	Dizziness	Vision Disturbance
Oxybutynin IR	71	15	17	10
Oxybutynin XL	61	13	6	14
Oxybutynin TDS	7	3	NR	3
Oxybutynin gel	10	1	3	3
Tolterodine	35	7	5	3
Tolterodine LA	23	6	2	4
Trospium chloride IR	20	10	NR	1
Trospium chloride XR	11	9	NR	2
Solifenacin	20	9	2	5
Darifenacin ER	24	18	2	2
Fesoterodine ER	27	5	NR	3
Mirabegron ER	3	3	3	NR
Vibegron	<1	2	<1	<1

IR, immediate release; LA, long acting; NR, not reported; TDS, transdermal system; XL, extended release; XR/ER, extended release.

[a] All values constitute mean data, predominantly using product information from the manufacturers.

Other Anticholinergics and Antimuscarinics

Tricyclic antidepressants are generally no more effective than oxybutynin IR, and give bothersome and potentially serious adverse effects (eg, orthostatic hypotension, cardiac conduction abnormalities, dizziness, and confusion). They are also potentially life-threatening in overdose. Therefore, their use should be limited to individuals who have one or more additional medical indications for these agents (eg, depression or neuropathic pain); patients with mixed UI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly those with nocturnal incontinence associated with altered sleep patterns. Desipramine and nortriptyline have lower incidences of adverse effects; they may be preferred over imipramine and doxepin. However, because of their lower anticholinergic activity, they may not be as effective. Propantheline, flavoxate, dicyclomine, and hyoscyamine are not recommended for urgency UI.

Botulinum Toxin A

Enthusiasm is considerable for the application of botulinum toxin A for treatment of voiding dysfunction. Botulinum toxin is a naturally occurring powerful muscle relaxant produced by *Clostridium botulinum*. Injected into smooth or striated muscle, botulinum toxin acts as a neurotoxin by temporarily paralyzing the muscle. The mechanism of action of the paralytic effect is generally ascribed to prevention of the release of the neurotransmitter acetylcholine into the synapse at the neuromuscular junction, although other pathways in neurotransduction may also be affected.

This compound is commercially produced for medical use in a number of conditions such as muscle spasticity, hyperhidrosis, and cosmetic reduction of skin wrinkles. It is indicated for the treatment of detrusor overactivity associated with neurologic condition and OAB.[62,70,71] Intradetrusor onabotulinumtoxin A is recommended by AUA as the third-line treatment in adult patients with refractory OAB.[21] In the lower urinary tract, it has also been used to treat external urethral sphincter spasticity by direct injection into the external urethral sphincter.

Botulinum toxin is delivered into the detrusor muscle (intravesical injection) using a cystoscope equipped with a needle. The usual dosage is between 100 and 300 units/session. It is injected through the needle directly into the bladder muscle in 10 to 30 injections spaced over 5 to 10 minutes. The procedure is carried out as an outpatient procedure without general anesthesia. The duration of therapeutic effect varies, lasting usually from 4 to 8 months. Repeat injections are necessary to maintain the beneficial effects.[71]

The adverse effects of botulinum toxin A when used in the urinary tract most frequently include dysuria, hematuria, urinary tract infection, and urinary retention. Urinary retention occurs in up to 20% of treated individuals and persists until the paralytic effects have worn off (up to 6-8 months). Therapeutic and adverse effects may not become evident for 3 to 7 days, presumably because this period of time is required for uptake of the toxin following injection.[62,71]

Intravesical (ie, bladder) injection of botulinum toxin A in patients with refractory OAB resulted in increased bladder capacity, increased bladder compliance, and improved quality of life.[62,71] Adverse effects include urinary tract infection and urinary retention.[71] Comparative data with placebo and other interventions, long-term safety and efficacy outcomes, and data regarding the optimal dose of botulinum toxin for idiopathic OAB are needed.

An alternative mechanism of delivery other than intravesical injection would greatly improve the appeal of this agent as needle injection can be painful in some individuals. Results of an open-label trial of intravesical botulinum toxin A in dimethylsulfoxide in 21 women with refractory idiopathic detrusor overactivity demonstrated a significant reduction in the frequency of incontinence episodes without any effect on postvoid residual urine volumes.[72] Further studies are needed in this regard.

Catheterization Combined with Medications

Patients with UUI and an elevated postvoid residual urine volume due to retention may require intermittent self-catheterization along with frequent voiding between catheterizations. If intermittent catheterization is not possible, surgical placement of a suprapubic catheter may be necessary. Use of a chronic indwelling catheter should be avoided because of the increased occurrence of urinary tract infections and nephrolithiasis.

Regardless of catheterization status, patients may experience symptom relief with judicious use of oxybutynin (IR, XL, or TDS formulations), tolterodine (IR or LA formulations), trospium chloride, solifenacin, fesoterodine, darifenacin, or mirabegron, as these agents relax the detrusor muscle and enhance bladder storage. Patients with UUI and symptoms of urinary retention may also benefit from an α-adrenergic receptor antagonist that relaxes the internal bladder sphincter (eg, prazosin, terazosin, doxazosin, tamsulosin, silodosin, and alfuzosin). Although theoretically of benefit, bethanechol, a cholinergic agonist, has not been demonstrated effective in improving bladder emptying in well-done trials. In addition, it causes numerous bothersome (eg, muscle and abdominal cramping and diarrhea) and potentially life-threatening adverse effects and should not be used in patients with asthma or heart disease.[22]

Urethral Underactivity

⑦Urethral underactivity, or SUI, may be aggravated by agents with α-adrenergic receptor blocking activity, including prazosin, terazosin, doxazosin, tamsulosin, alfuzosin, silodosin, methyldopa, clonidine, guanfacine, and labetalol. The goal of therapy for SUI is to improve the urethral closure mechanism by stimulating α-adrenergic receptors in the smooth muscle of the bladder neck and proximal urethra, enhancing the supportive structures underlying the urethral epithelium, or enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex.[73]

Estrogens

Local and systemic estrogens have been used extensively for the pharmacologic management of SUI since the 1940s. Estrogens are believed to work via several mechanisms, including enhancement of the proliferation of urethral epithelium, local circulation, and numbers and/or sensitivity of urogenital α-adrenergic receptors. However, a trial has questioned whether estrogens exert a stimulatory effect on vaginal collagen production, at least over the short-term.[74]

A meta-analysis of 34 trials evaluating the use of local or systemic estrogen therapy on UI in postmenopausal women found that systematic administration of estrogen alone or in combination with progesterone resulted in UI worsening.[75] In fact, observational studies have documented that oral or systemic estrogen use is associated with an increased risk of UI compared with that in nonusers.[76] There was some evidence that vaginal estrogen (vaginal cream or pessaries) may improve UI, and reduce urgency and frequency. The long-term effects of this therapy in older women are unknown. A recent meta-analysis of 17 trials of local estrogen compared to placebo or no treatment found beneficial effects on UI and OAB symptoms and some urodynamic parameters.[77] Different forms of vaginal estrogen (ring, pessary) have similar improvements in urinary symptoms (SUI, UUI, frequency, urgency). Studies comparing vaginal estrogen alone or in combination with antimuscarinic drugs (tolterodine or oxybutynin) or pelvic floor muscle exercises found greater improvement in subjective measures of UI in the combination approach. If estrogens are to be used for treatment of UI or OAB in postmenopausal women, only topical products should be administered, potentially combined with other treatment modalities such as pelvic floor muscle exercises or antimuscarinic drugs.

α-Adrenergic Receptor Agonists

Numerous open trials have supported the use of a variety of α-adrenergic receptor agonists in SUI, including ephedrine, norfenefrine, phenylpropanolamine, and midodrine. Phenylpropanolamine was withdrawn from the US market in 2000 because of a risk for stroke in women using the agent.[78] Patients may obtain the drug from international sources or via Internet. If so, individuals with the contraindications listed later in the chapter (especially coronary artery disease and/or cardiac arrhythmias) should be warned against self-treatment with this or other α-adrenergic receptor agonists.

Placebo-controlled comparative trials with phenylpropanolamine, norfenefrine, and norephedrine support the modest efficacy of these agents for treatment of mild or moderate SUI.[79] These agents have been found to variably affect maximum urethral closure pressure and functional urethral length. Adverse effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness. Contraindications to the use of these agents include the presence of hypertension, tachyarrhythmias, coronary artery disease, myocardial infarction, cor pulmonale, hyperthyroidism, renal failure, and narrow-angle glaucoma.

Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α-adrenergic receptor agonist exceed those of the individual therapies in SUI.[79] In general, combination therapy has resulted in somewhat superior clinical and urodynamic responses compared with monotherapy, including severity of complaints, amount of urine lost per episode, number of daily voluntary micturitions, number of leakage episodes per day, patient preference, pad use, maximum urethral closure pressure, functional urethral length, and pressure transmission ratio.

Duloxetine

Duloxetine, a dual inhibitor of serotonin and norepinephrine reuptake (SNRI), was approved in 2004 for treatment of depression and painful diabetic neuropathy in the United States.[80] It is approved for SUI in Europe only. It is believed to affect central serotoninergic and noradrenergic regions, which are involved in ascending and descending control of urethral smooth muscle and the external urethral sphincter. These mechanisms facilitate the bladder-to-sympathetic reflex pathway, increasing urethral and external urethral sphincter muscle tone during the storage phase.

Duloxetine is metabolized by CYP2D6 and 1A2 enzymes to form multiple metabolites and then eliminated in the urine. Duloxetine may increase the concentrations, drug exposure, and half-lives of CYP2D6 substrates (eg, desipramine). Meanwhile, the drug concentration of duloxetine can be increased by CYP2D6 inhibitors (eg, paroxetine) and CYP1A2 inhibitors (eg, fluvoxamine).[80] Moderate hepatic dysfunction (Child-Pugh class B) significantly increases mean AUC and terminal disposition half-life of duloxetine. Mild or moderate renal impairment (creatinine clearance 30-80 mL/min [0.50-1.33 mL/s]) does not affect drug disposition. In severe renal impairment (hemodialysis patients), mean peak plasma concentration and AUC are both increased 100%, whereas metabolite concentrations are increased up to 900%.[80]

In six large, double-blinded, randomized, placebo-controlled clinical trials that evaluated duloxetine for SUI, duloxetine therapy produced significant reductions in UI episode frequency and number of micturitions per day, improvement in incontinence quality-of-life questionnaire scores and patient self-assessment, and increase in mean micturition interval. Results were independent of baseline UI severity (severity based on incontinent episode frequency). Significant intergroup differences were seen by week 4. However, cure rates were generally not improved by duloxetine. When evaluating the absolute differences between treatments, the actual benefit of duloxetine was generally quite modest. Duloxetine also reduced incontinence episodes and improved quality of life in men with SUI after radical prostatectomy.[81]

A randomized, placebo-controlled clinical trial evaluated the effects of duloxetine (80 mg daily), pelvic floor muscle training (PFMT), and the combination of both modalities on incontinent episode frequency, incontinence-related quality of life, pad use, and patient global impression of change. Sham PFMT was used in the placebo group. Results indicated that duloxetine plus PFMT were probably additive in effect and that combination therapy afforded greater improvement than either monotherapy.[82]

The adverse events associated with duloxetine may make adherence problematic. In the SUI trials, treatment-emergent adverse events occurred in 68% to 93% of duloxetine and 50% to 72% of placebo recipients. Premature study withdrawal rates (due to adverse events) were as high as up to 33%. The most common adverse events reported with duloxetine were nausea (≤46%), headache (≤27%), constipation (≤27%), dry mouth (≤22%), and insomnia (≤14%). Of interest, the drug may be associated with small increases in blood pressure (such as venlafaxine, another SNRI) and withdrawal symptoms (sleep disturbances). Unfortunately, adherence to long-term therapy is quite poor due to a combination of adverse events and lack of efficacy.[83]

Despite these negatives, duloxetine is the first drug approved by a regulatory agency for treating SUI in Europe. Based on studies conducted to date, a dosage regimen of 40 to 80 mg/day (in one or two doses) is reasonable. Gradual dose titration (40 mg daily for 2 weeks, then 80 mg daily) helps reduce the risks of nausea, dizziness, and premature drug discontinuation. If cessation of duloxetine is desired, consider tapering the dosage by 50% for 2 weeks before discontinuation to avoid withdrawal symptoms.

Venlafaxine

Venlafaxine is another SNRI. A double-blind, randomized, placebo-controlled clinical trial has demonstrated the benefit of venlafaxine 75 mg once daily for 12 weeks over placebo in terms of incontinence episode frequency, voiding interval, quality of life, and patient global impression of improvement. Nausea occurred in 40% of the venlafaxine group compared with 15% of the placebo group.[84]

Overflow Incontinence

Overflow incontinence secondary to benign or malignant prostatic hyperplasia may be amenable to pharmacotherapy. For management of malignant prostatic disease, see Chapter 154, “Prostate Cancer.” The pharmacotherapy of BPH is discussed in Chapter 104.

EVALUATION OF THERAPEUTIC OUTCOMES

⑧Assessment of patient outcomes should include efficacy, side effects, adherence, and quality of life. During long-term management of UI, patient-specific clinical signs and symptoms of most distress (“bother”) to the individual must be monitored. A daily diary may be useful in this regard. Some of the short-form instruments used in incontinence research for measuring symptom impact and condition-specific quality of life can be used in clinical monitoring. In addition, quantitating the use of ancillary supplies, such as pads, may be useful.

⑨The main goal of therapy is to minimize the signs and symptoms most bothersome to the patient, as well as the use of pads and other ancillary supplies or devices. Total elimination of UI signs and symptoms may not be possible, and patients and practitioners need to mutually establish realistic goals of therapy. Because the therapies for UI frequently have nuisance adverse effects (eg, anticholinergic effects such as dry mouth, constipation, and sedation) that may compromise regimen adherence, the presence and severity of adverse effects must be carefully elicited at each visit to the healthcare practitioner. Queries of the patient and caregiver regarding CNS effects are important in elderly or frail patient as these effects can be severe enough to cause loss of independent living skills. Emergence of adverse effects may necessitate drug dosage adjustment or use of alternative strategies (eg, chewing sugarless gum, sucking on hard sugarless candy, or use of saliva substitutes in xerostomia) or even drug discontinuation. Patient should be encouraged to persist with a particular treatment for 4 to 8 weeks before declaring treatment failure. Nonresponders to an antimuscarinic should be offered at least one other antimuscarinic and/or dose modification attempted to obtain a better balance between efficacy and side effects.

ABBREVIATIONS

ACE	angiotensin-converting enzyme
AUA	American Urological Association
AUC	area under the plasma or serum concentration-versus-time curve
BPH	benign prostatic hyperplasia
CNS	central nervous system
CYP	cytochrome P450
DD01	5-hydroxymethyl metabolite
ER	extended-release
EStim	electrical stimulation
FDA	Food and Drug Administration
IR	immediate release
LA	long acting

SELF-ASSESSMENT QUESTIONS

1. Which of the following groups has the highest prevalence of urinary incontinence?

    A. Women of childbearing age

    B. Women age 70 years and older

    C. Men treated for prostate cancer

    D. Men aged 70 years and older

2. A 65-year-old woman reports leaking moderate amounts of urine several times during the day after feeling a sudden urge to urinate. She also reports leaking small amounts of urine after she coughs or sneezes. She is using 3 pads per day for incontinence. Urinalysis is unremarkable and her postvoid residual in 20 mL. What type of urinary incontinence does she most likely have?

A. Stress

B. Urgency

C. Overflow

D. Mixed

3. An 85-year-old man living in a nursing home has several episodes of incontinence daily. He has moderate dementia and uses a walker when ambulating. He needs prompting from caregivers to use the bathroom. What type of urinary incontinence should he be treated for?

   A. Stress

   B. Urgency

   C. Disability associated

   D. Overflow

4. A 32-year-old woman complains of losing small amounts of urine while she exercises and after she coughs or sneezes. She denies urinary frequency or having a compelling urge to urinate. She lost a small amount of urine during the cough test. She delivered three babies vaginally, the most recent being 1 year ago. What is the first-line treatment for her incontinence?

   A. Pelvic floor muscle exercises

   B. Bladder training

   C. An antimuscarinic drug

   D. Timed voiding

5. A 52-year-old postmenopausal woman reports losing small-to-moderate amounts of urine several times a day after having a strong urge to urinate. In an attempt to avoid these leaks, she is urinating every 2 hours. She is awakened at least two times each night with a strong urge to urinate and often leaks before she can get to the toilet. She is using 3 to 4 large absorbant pads a day to contain her leaks. Urinalysis is unremarkable and her post-void residual is 25 mL. Which is the best initial treatment for her?

   A. Bladder training

   B. Percutaneous tibial nerve stimulation

   C. Timed voiding

   D. Pelvic floor muscle exercises

6. A 60-year-old woman is diagnosed with overactive bladder with occasional urge urinary incontinence during daytime (once or twice weekly). Her past medical history includes congestive heart failure, chronic constipation, falls, glaucoma, hypothyroidism, spinal stenosis, and osteoarthritis. She is taking appropriate medications for her health conditions. She prefers an oral treatment that is least likely to cause constipation, dry mouth, or other anticholinergic side effects. She has a good prescription plan. You recommend:

   A. Imipramine

   B. Vibegron

   C. Oxybutynin IR

   D. Darifenacin

7. The most appropriate agent for managing atonic bladder or overflow incontinence is:

   A. Imipramine

   B. Topical estrogen

   C. Pseudoephedrine

   D. Bethanechol

8. A 75-year-old woman is diagnosed with overactive bladder with urge incontinence and nocturia. She has type 2 diabetes mellitus, hypertension, congestive heart failure, and insomnia due to home relocation one week ago. Her current medications include aspirin 81 mg daily, metoprolol extended release 100 mg daily, enalapril 5 mg daily, furosemide 40 mg daily, metformin 500 mg with breakfast, and melatonin 5 mg at bedtime. She reports nocturia one to two times per night since her doctor increased the dose of furosemide last month for lower extremity edema. Otherwise, she tolerates all of her medications. You recommend to:

   A. Switch furosemide to bumetanide

   B. Check glucose levels and HbA1c

   C. Start estradiol topical cream

   D. Switch melatonin to clonazepam

9. A 60-year-old patient is referred to the pharmacy clinic to initiate an appropriate drug therapy of overactive bladder. She has difficulty swallowing, and requires medications to be crushed. She is 5 ft 2 in. (157 cm) tall, and weighs 135 lb (61 kg). Her serum creatinine is 3 mg/dL (265 μmol/L). You recommend:

   A. Fesoterodine 8 mg daily

   B. Mirabegron 25 mg daily

   C. Solifenacin 10 mg at bedtime

   D. Trospium 20 mg at bedtime

10. A 55-year-old woman with potentially limited health literacy complains of "having water problem." She complains of urinary urgency and frequency. She has no episode of urinary incontinence so far. She has not visited physicians for the past five years. She has self-initiated therapy with over-the-counter product oxybutynin 3.9 mg/day patch. She applies one patch every day for the past 3 days. She notices a little improvement in symptoms, but also reports dry mouth. Today her physician ruled out urinary tract infection, and diagnosed her to have overactive bladder. She has no prescription insurance, and wants "a medication that helps and does not cost too much." Which of the following is most appropriate to initiate now?

    A. Counsel the patient on appropriate use of oxybutynin patch

    B. Add over-the-counter pseudoephedrine 15 mg three times daily

    C. Switch oxybutynin patch to mirabegron 25 mg daily

    D. Switch oxybutynin patch to cranberry extract daily

11. Following the initiation of behavioral therapy for urge urinary incontinence, a patient requests additional treatment. Appropriate pharmacologic therapy in this setting is:

    A. Phenylpropanolamine

B. Solifenacin

C. Bethanecol

D. Oral estrogen

E. Tamulosin

12. A 50-year-old premenopausal woman presents to her primary provider with bothersome symptoms of stress urinary incontinence. She reports losing a few drops of urine 2 to 4 times a week. Her physical examination is unremarkable. Appropriate initial therapy consists of behavioral modification and:

A. Absorbent pad

B. Pelvic floor muscle exercises

C. Diphenhydramine

D. Darifenacin

E. Vaginal estrogen

13. An 80-year-old man residing in a nursing home has urgency and urge incontinence that results in loss of urine several times a day as well as nocturnal enuresis. He voids every 5 to 6 hours during the day. This resident also has hypertension, heart failure, severe arthritis, diabetes, and mild dementia. The most appropriate choice of treatment is:

A. An antimuscaric agent

B. Suprapublic catheter

C. Timed toileting

D. Absorbent pads

E. Bed alarm

14. A 55-year-old postmenopausal, obese woman who smokes complains of small volume of urine leakage when she coughs or laughs. She reports no urinary frequency or incontinent episodes at night. She gave birth to two children in her 30s. Her risk factors for stress incontinence include:

A. Postmenopausal status

B. Childbirth

C. Obesity

D. Age

E. All of the above

15. Which of the following statements about mirabegron is correct?

A. It is a β_3-adrenergic antagonist.

B. It has been approved for stress incontinence in Europe only.

C. It should be swallowed whole.

D. Its use is associated with bradycardia.

E. It should not be administered concomitantly with oral estrogen replacement.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The prevalence rate of incontinence is three times higher in women than in men. Women aged 70 years and older having the highest prevalence estimated at 40%.
2. **D.** Mixed urinary incontinence is defined as having symptoms of both stress and urgency urinary incontinence. Symptoms of urgency incontinence include leaking moderate amounts of urine after feeling a sudden urge to urinate. Symptoms of stress incontinence include losing small amounts of urine after coughing and sneezing.
3. **C.** Older people with cognitive and physical impairments have a high likelihood of experiencing disability associated urinary incontinence, which is defined as the complaint of urinary incontinence in the presence of a functional inability to reach a toilet or urinal in time because of a physical or mental impairment.
4. **A.** This patient is demonstrating symptoms of stress urinary incontinence, which is the most common type of incontinence in women of child-bearing age, particularly if they have had multiple vaginal deliveries. First line treatment for stress incontinence is pelvic floor muscle exercises. Bladder training and timned voiding are not appropriate, as she is not experiencing urinary frequency or urgency. Antimuscarinic drugs are also not appropriate as they are used to treat urgency incontinence.
5. **A.** This woman is experiencing urgency urinary incontinence as evidenced by urinary frequency, nocturia, and a sense of urgency prior to leaking. The best initial treatment to recommend is bladder training, which involves scheduled toiletings with progressive voiding intervals; the use of urgency suppression strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques. She has developed a maladaptive behavior of urinating frequently that will be helped with bladder training.
6. **B.** Vibegron is a β_3-adrenergic agonist. It is least likely to cause anticholinergic side effects.
7. **D.** Bethanechol can be used for overflow urinary incontinence (atonic bladder) if no contraindication exists.
8. **B.** Hyperglycemia may exacerbate polyuria. Optimizing blood glucose control is an item to address during diagnostic evaluation of urinary incontinence.
9. **D.** The correct dose of trospium IR is 20 mg at bedtime in patients with creatinine clearance less than 30 mL/min (0.50 mL/s). Immediate-release products can be crushed.
10. **A.** Oxybutynin patch should be applied twice per week (every 3-4 days), not once daily. Proper patient education is important, taking in consideration of the level of health literacy in this patient. Over-the-counter oxybutynin patch is less expensive than prescription drugs, mirabegron, and darifeancin. The patch formulation produces less dry mouth.
11. **B.** Urgency incontinence calls for treatment with an antimuscarinic agent.
12. **B.** Pelvic floor muscle exercises can be helpful for stress incontinence.
13. **C.** Timed toileting can be helpful in older adults with frailty. Nonpharmacologic interventions should be considered as first-line treatment.
14. **E.** Decline in estrogen level in postmenopausal women, history of childbirth, obesity, and age (postmenopausal) are risk factors for stress incontinence.
15. **C.** Mirabegon should be swallowed whole. Do not chew, cut, or divide.

Chapter 107: Systemic Lupus Erythematosus

Beth H. Resman-Targoff

KEY CONCEPTS

KEY CONCEPTS

① Systemic lupus erythematosus (SLE) is considered a disease primarily of young women, but it can occur in anyone. The prevalence and severity vary with sex, race, ethnicity, and socioeconomic factors.

② Understanding the etiology of SLE and environmental factors that can initiate or exacerbate the disease may make it possible to avoid those triggers.

③ SLE is an autoimmune disease characterized by the presence of autoantibodies, some of which may play a role in the pathogenesis of the disease. An understanding of disease mechanisms can lead to targeted drug therapy.

④ SLE is a multisystem disease that can involve almost any organ and may present in many different ways. Therapy is determined by the manifestations in each patient, which may change and fluctuate in severity over time.

⑤ Lifestyle changes can modify risk factors for SLE flares and complications.

⑥ The overall goals of therapy are to prevent disease flares and involvement of other organs, decrease disease activity and prevent damage, achieve and maintain remission, reduce use of corticosteroids, and improve quality of life, while minimizing adverse drug reactions and costs. Most patients with SLE should receive hydroxychloroquine alone or in combination with other therapy appropriate for the disease manifestations.

⑦ Pregnancy planning is essential for good outcomes. Pregnancy outcomes are best when the disease is controlled before conception. Drugs used to treat SLE may adversely affect fertility and the fetus.

⑧ Antiphospholipid antibodies are associated with arterial and venous thrombosis and obstetric complications.

⑨ Many drugs can induce a lupus-like syndrome. The manifestations and laboratory findings may be different between the traditional drug-induced lupus and that seen with tumor necrosis factor-alpha inhibitors.

⑩ Since SLE can present in many different ways, it is difficult to design standard response criteria. The development of appropriate criteria is essential for the approval of new drugs.

BEYOND THE BOOK

BEYOND THE BOOK

Lupus Canada: review the Living with Lupus Section (https://lupuscanada.org/living-with-lupus/)

Summarize what you learned about SLE from the Personal Stories section (https://lupuscanada.org/living-with-lupus/personal-stories/).

What questions would you have if you developed lupus?

INTRODUCTION

Systemic lupus erythematosus (SLE) is an autoimmune disease associated with autoantibody production. The term “lupus” (Latin for wolf) was first used in medieval Europe to describe erosive lesions that looked like skin that had been bitten by a wolf. In the 1800s, it was recognized that other organs may be affected and we now know that SLE is a multisystem disease. The common finding in SLE is the production of autoantibodies.[1] This is an exciting time in the management of SLE because a better understanding of disease mechanisms has led to the development of new drugs. In addition, new response criteria are evolving to show efficacy of drugs, even with the background of standard therapy. This led to the first approval of a drug for the treatment of SLE in over 50 years with a new indication 9 years later. Two more drugs were approved for SLE management. Despite these advances, control of this disease remains a challenge. It has a myriad of manifestations and many of the drugs used to treat it are not approved for this indication. As a result, the dosing of many of the drugs considered to be standard-of-care therapy must be personalized.

EPIDEMIOLOGY

① Systemic lupus erythematosus occurs most frequently in women of reproductive age (15-45 years).[2] This is especially characteristic of the disease in nonWhite women. The epidemiology of SLE depends on the population studied, method used to define cases, and definition of SLE.[3] These can have profound effects on estimates of incidence and prevalence, disease activity and severity, and mortality. In the US Medicare population, the incidence ranges from 3.7 to 49 per 100,000 person-years and the prevalence is 48 to 366.6 per 100,000 persons. The global incidence ranges from 1.5 to 11 per 100,000 person-years with a prevalence of 13 to 7,713.5 per 100,000 individuals, but there are little data from some parts of the world.[3] Rates are nine times higher in women than in men so the overall population statistics can be misleading.[2] It is affected by ethnicity, which includes genetic, geographic, cultural, social, and other aspects within a group. Rates are higher in nonWhite than in the White population.[4] It is most common in those of African origin, but is also more common in people of Asian, Arab, and Hispanic background, and Native American people (called First Nations in Canada) than in White people.[4,5] Most people are of mixed race, so race by itself can be difficult to analyze. NonWhite patients tend to have an earlier onset, more severe disease, and a higher mortality rate, but it can be difficult to separate out the influence of socioeconomic factors, comorbidities, and access to medical care.[3] The disease tends to be more severe in men and children, and those with onset at a later age (over 50 years) have poor outcomes.[4]

Survival rates have improved with better therapy and earlier diagnosis and initiation of treatment. The standardized mortality ratio for SLE is two to three times higher than in the general population, most related to more cardiovascular and renal disease and infections.[3] Overall SLE survival is 95% at 5 years and 92% at 10 years after diagnosis. This is reduced to about 88% at 10 years with lupus nephritis and even less than that in African American patients with lupus nephritis.[6] The survival rate may be lower in men, but the small number of males in most studies makes this difficult to determine.[4]

ETIOLOGY

② The exact etiology of SLE is unknown but many factors play a role in the disease. Some are predisposing factors and others are involved in the disease mechanisms. Categories of these elements include genetic influences, epigenetic regulation of gene expression, environmental factors, hormones, and abnormalities in immune cells and cytokines.[7]

The incidence of SLE is increased in affected families. First-degree relatives of patients with SLE are 20 times more likely to develop the disease than those in a general population.[8] Ten percent of patients with SLE have relatives with the disease. The concordance rate is 24% to 69% for identical twins and 2% to 5% for fraternal twins and other full siblings.[9] The genetic predisposition to SLE results from the interplay between several genes. In rare cases, it results primarily from a single abnormal gene.[7] The major histocompatibility complex (MHC) class II alleles HLA-DR2 and HLA-DR3 are known to be linked to SLE. An increasing number of other gene loci have been associated with the disease.[10] Gene expression is regulated by deoxyribonucleic acid (DNA) methylation and histone modifications. These epigenetic changes can cause alterations that may influence SLE. Interestingly, hydralazine and procainamide, two drugs that may induce lupus, inhibit DNA methylation.[11]

In a genetically susceptible individual, environmental triggers can initiate or exacerbate the disease. The type of trigger may influence specific organ involvement. Cigarette smoke has many toxic combustion byproducts that can react with DNA molecules and increase cell apoptosis, NETosis, or necrosis. Chronic smokers with greater than ten pack-year smoking history are more likely to have elevated titers of anti-double-stranded DNA (anti-dsDNA) and antiphospholipid antibodies.[12,13] Cigarette smoking damages the skin and worsens disease and quality of life.[14] Ultraviolet light can cause DNA damage and keratinocyte apoptosis with the release of cytokines and stimulation of the immune system causing skin injury and possible systemic flares.[14] Viruses may trigger SLE and the Epstein–Barr virus has been implicated.[10] Other implicated triggers include other infections; air pollution; medications; silica and asbestos; heavy metals such as uranium, cadmium, and lead; and polycyclic aromatic hydrocarbons used to make dyes, plastics, and pesticides.[14–16]

The higher prevalence in women suggests that hormones such as estrogens and progesterones play a role in SLE, but the presence of the X chromosome may also contribute. The TLR7 gene on the X chromosome increases susceptibility to autoimmune disease. The incidence of SLE is increased 14-fold in men with Klinefelter (XXY) syndrome and 2.5-fold in women with XXX syndrome, and decreased in women with Turner (XO) syndrome as compared to normal subjects.[17]

PATHOPHYSIOLOGY

③ Systemic lupus erythematosus is a multisystem disease characterized by disorders of the innate and adaptive immune systems (Fig. 107-1). T- and B-lymphocyte activation and signaling are altered in SLE and there is abnormal clearance of apoptotic debris containing nuclear material which can stimulate immune responses.[10] The number of plasma cells is increased in active SLE and these cells produce autoantibodies, which can cause tissue damage. Neutrophil dysfunction can increase the risk of infection.[18] Antibodies directed at dsDNA are seen in about 60% to 70% of patients with SLE and less than 0.5% of patients without the disease.[10] The titers of anti-dsDNA may fluctuate with disease activity and may predict disease flare. Some autoantibodies may play a role in the pathogenesis of clinical features of SLE; these autoantibodies may target Ro/SSA (antigen Ro/Sjögren syndrome A, ribonucleoprotein complex), La/SSB (antigen La/Sjögren syndrome antigen B, RNA-binding protein), C1q (subunit of the C1 complement component), Sm (nuclear particles), *N*-methyl-d-aspartate (NMDA) receptor (amino acid released by neurons), phospholipids, nucleosomes (from apoptotic cellular debris), and histones (protein core of nucleosomes). The autoantibodies can be present for many years before SLE is clinically apparent and they may be associated with specific organ involvement, such as anti-dsDNA, anti-Ro, anti-La, anti-C1q, and anti-Sm with lupus nephritis, and anti-NMDA associated with central nervous system (CNS) lupus.[10]

FIGURE 107-1

Pathogenesis of systemic lupus erythematosus (SLE). Pathogenesis is related in large part to the production of increased quantities and immunogenic forms of nucleic acids and other self-antigens, which drive autoimmune-inducing activation of innate immunity, autoantibodies, and T-cells. Interactions between genes, environment, and epigenetic changes drive increased autophagy, Ag presentation, neutrophil NETosis, autoantibody formation with increased plasma cells, and production of pathogenic effector T-cells in Th1, Th17, and Tfh subsets, with ineffective regulatory networks. (Ag, antigen; C1q, complement system; C2, C4, complement components; CNS, central nervous system; DC, dendritic cell; EBV, Epstein-Barr virus; HLA, human leukocyte antigen; IFN, interferon UV, ultraviolet.) The exact mechanism of autoantibody tissue destruction is unclear. Immune complexes form when autoantibodies bind to nuclear material and deposit in tissues.[10] They activate the complement cascade, leading to an influx of inflammatory cells and tissue injury.[18] Autoantibodies might also directly react with proteins in tissues. Antibodies to blood cells can cause cytopenias.[10] Antibodies against phospholipids can lead to thrombosis and fetal loss.[19]

T-cell abnormalities contribute to the immune disorders observed in SLE. There are increased T helper cells type 2 and 17 and diminished number and function of T regulatory (Treg) cells. Cytokines, such as tumor necrosis factor-alpha (TNF-α), interferon-gamma, and interleukin-10, produced by activated T-cells can stimulate B-cells.[10]

Cytokines play multiple roles in SLE and contribute to inflammation and tissue damage. Interleukin-10 stimulates B-cell proliferation and autoantibody production in renal cells and may affect skin and joint symptoms.[10] Increased T-cell production of interleukin-17 correlates with disease activity and may contribute to kidney and other tissue damages.[10,18] Interleukin-2 is decreased, which is important for Treg function and restriction of interleukin-17.[18] Plasmacytoid dendritic cells secrete type I interferon, which has a role in the pathogenesis of SLE and may correlate with disease severity. High concentrations of type I interferon are associated with mucocutaneous inflammation and high interferon-γ with nephritis and arthritis.[20] B-lymphocyte stimulator (BLyS), also known as B-cell activating factor of the TNF family (BAFF), increases survival and promotes differentiation of B-cells.[21] Interleukin-6 promotes production of antibodies and may play a role in lupus nephritis.[10] The role of TNF-α in SLE is unclear. It is harmful in some patients and protective in others.[10]

CLINICAL PRESENTATION

4 Systemic lupus erythematosus is an autoimmune disease that can involve almost any organ and may present in different ways. This can make it difficult to establish a diagnosis and an extensive workup may be needed to determine the full extent of involvement and to exclude other possible etiologies for the manifestations. Fatigue is common, but does not help distinguish SLE from other diseases.[22] SLE should be considered for patients with arthritis, mucocutaneous features, noninfectious fever, leukopenia, hemolytic anemia, serositis, and unexplained proteinuria.[22] Arthritis is experienced by 85% of patients with SLE.[13] SLE may present differently in men and women. In a Swedish study, men were found to have more severe disease with increased propensity for renal disorders and serositis. Skin manifestations were more common in women.[23] Race and ethnicity may also affect the specific manifestations and severity.[13]

Disease manifestations fluctuate with 70% of patients experiencing a relapsing-remitting course.[13] The presence of ANA may be used as a screening test for SLE. Most patients with SLE have these antibodies, but they are not specific for the disease.[24]

An international group of SLE researchers developed and validated criteria for classification of SLE in 2012. These are called the Systemic Lupus International Collaborating Clinics (SLICC) classification criteria and were developed to identify patients with the disease for clinical studies. *They are not intended to establish a diagnosis in an individual patient* but may help assess the likelihood that a patient has SLE. The widely used American

College of Rheumatology (ACR) criteria were developed in 1982 and revised in 1997. The 1997 version was not validated. The SLICC criteria are more clinically relevant and sensitive than the 1997 ACR criteria. When validated, the SLICC criteria had a sensitivity of 97% and specificity of 84% compared to 83% and 93% for the 1997 ACR criteria.[24,25] The number of criteria was expanded from 11 to 17 and, unlike the 1997 ACR criteria, they are divided into clinical and immunologic parameters. The 1997 ACR criteria required four of the 11 elements to be present, serially or simultaneously. To satisfy the SLICC criteria, a patient must still meet at least four of the elements, but now these must include at least one clinical and one immunologic criterion or the patient must have biopsy-proven lupus nephritis with positive ANA or anti-dsDNA antibodies.[25] It may be possible to classify patients earlier in their disease course as having SLE with the SLICC criteria. An updated version of the SLICC criteria added weights to the variables.[26] These have both a sensitivity and specificity of 89%, but were not considered superior to the original SLICC criteria.[26] New classification criteria that focus on early diagnosis were developed through a collaboration of the ACR and the European Alliance of Associations for Rheumatology (formerly European League Against Rheumatism) (EULAR).[24] An abbreviated version of the SLICC criteria, with comparison to the 1997 ACR and the EULAR/ACR criteria, is shown in Table 107-1. The EULAR/ACR criteria require an entry criterion of an ANA positive at a titer of at least 1:80. They include seven clinical and three immunology domains with points assigned only for the most heavily weighted element in each domain. The elements could be present on at least one occasion and must not have an alternative explanation. There must be at least one clinical criterion. A score of at least 10 is required for the classification of SLE. These have a sensitivity of 96% and a specificity of 93%. The criteria worked well in all genders, ethnicities, ages, and disease duration.[22] Some may feel that calculation of weights is more cumbersome. Ultimately, the choice of criteria depends on the study investigators and the population studied.[26]

TABLE 107-1

2012 Systemic Lupus International Collaborating Clinics Classification Criteria for Systemic Lupus Erythematosus (SLICC) Versus 2019 EULAR/ACR Criteria for SLE

Clinical Criteria-SLICC	Clinical Domains-EULAR/ACR	Weight
1. Nonscarring alopecia 2. Oral OR nasal ulcers 3. Chronic cutaneous lupus/discoid rash 4. Acute/subacute cutaneous lupus/malar rash[a]/photosensitive rash[a] 5. Arthritis/synovitis or tenderness 6. Serositis (pleuritis, pericarditis) 7. Renal (urine protein-to-creatinine ratio [or 24-hour urine protein] representing 500-mg protein/24 hr OR red blood cell casts) 8. Neurologic (seizure, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, acute confusional state) 9. Leukopenia OR lymphopenia[b,c] 10. Thrombocytopenia[b,d] 11. Hemolytic anemia[b]	*Mucocutaneous* Non-scarring alopecia Oral ulcers Subacute cutaneous OR discoid lupus Acute cutaneous lupus *Musculoskeletal* Joint involvement *Serosal* Pleural or pericardial effusion Acute pericarditis *Renal* Proteinuria >0.5 g/24 h Renal biopsy Class II or V nephritis Renal biopsy Class III or IV nephritis *Neuropsychiatric* Delirium Psychosis Seizure	2 2 4 6 6 5 6 4 8 10 2 3 5 3 4 4 2

	Hematologic Leukopenia[c] Thrombocytopenia[d] Autoimmune hemolysis *Constitutional* Fever (temperature >101°F [38.3°C])	
Immunologic Criteria	**Immunology Domains**	**Weight**
1. Antinuclear antibody (ANA) 2. Anti-double-stranded DNA (dsDNA)[c] 3. Anti-Sm[c] 4. Antiphospholipid antibody (lupus anticoagulant, anticardiolipin, anti-β_2-glycoprotein I, false-positive rapid plasma reagin test for syphilis)[c] 5. Low complement (C3, C4, CH50) 6. Direct Coombs test (without hemolytic anemia)	*ANA at titer ≥ 1:80 required* *SLE-specific antibodies* Anti-dsDNA antibody OR Anti-Smith antibody *Antiphospholipid antibodies* Anticardiolipin antibodies OR Anti-β2GP1 antibodies OR Lupus anticoagulant *Complement proteins* Low C3 OR low C4 Low C3 AND low C4	6 2 3 4

[a] In the ACR Criteria, malar rash and photosensitivity are two separate criteria.

[b] In the ACR Criteria, hemolytic anemia, leukopenia, lymphopenia, and thrombocytopenia count as one criterion.

[c] Leukopenia is defined as <4,000 cells/mm^3 [4 × 10^9/L]; lymphopenia is <1,000 cells/mm^3 [1 × 10^9/L].

[d] Thrombocytopenia is defined as <100,000/mm^3 [100 × 10^9/L].

[e] In the ACR Criteria, anti-dsDNA, anti-Sm, and antiphospholipid antibody count as one criterion.

Data from References. 24–26.

The SELENA-SLEDAI Flare Index defines an SLE flare as “changes in the SLEDAI score and/or individual manifestations and/or changes in treatment and/or need for hospitalization and/or changes in PGA.”[13] The assessor must consider the increase in disease activity to be clinically significant, sufficient to consider a change or an increase in treatment. A need to increase a prednisone dose or hospitalization for SLE is especially pertinent.[13]

Some skin involvement is seen in up to 93% of patients with SLE and is the first sign of systemic disease in up to 25% of patients.[14] Cutaneous lupus is two to three times more common than SLE.[27] This can be disfiguring and affect a patient’s health-related quality of life.[28] Four main types of cutaneous lupus erythematosus have been observed. They may occur with or without SLE and one-third of patients have two or more forms of cutaneous lupus.[29] *Acute cutaneous* lupus erythematosus is typically seen in patients with SLE and is characterized by a photosensitive malar rash over the cheeks and nose with sparing of the nasolabial folds. This is commonly called a “butterfly” rash. The malar rash is present in up to 52% of patients with SLE at the time of diagnosis. There can also be a generalized form with erythematous macules and papules in a photodistributed pattern.[27] *Subacute cutaneous* lupus erythematosus is highly photosensitive and is manifested by annular or papulosquamous lesions that usually heal without scarring.[27] It can be accompanied by musculoskeletal complaints such as arthralgias and arthritis, and proteinuria.[30] About 60% to 80% of these patients are ANA positive and 70% have anti-Ro/SSA autoantibodies. It is often seen in young to middle-aged Caucasian women and is more common than other types of cutaneous lupus erythematosus in patients with drug-induced lupus. About half of patients with subacute cutaneous lupus erythematosus meet the criteria for SLE.[27] Many subtypes of *chronic* cutaneous lupus erythematosus have been identified. The most common is discoid lupus, which is confined to the head and neck in most patients, but can also affect mucosal surfaces. It carries a high risk for scarring alopecia.[27] Discoid lupus progresses to SLE in less than 5% of patients.[30] Discoid lupus is more common in African American patients with a 5.4-fold higher risk than in Caucasian patients.[14,31] Some consider *intermittent* cutaneous lupus erythematosus to be a fourth form of cutaneous lupus.[31]

CLINICAL PRESENTATION: Systemic Lupus Erythematosus

Symptoms

- Fatigue, depression, anxiety, photosensitivity, joint pain, headache, weight loss, nausea/abdominal pain

Signs

- Rash, alopecia, fever, oral and nasal ulcers, arthritis, renal dysfunction, seizure, psychosis, pleuritis, pleural effusion, cardiovascular disease, pericarditis/myocarditis, heart murmur, hypertension, anemia, leukopenia, thrombocytopenia, lymphadenopathy, Raynaud's phenomenon, vasculitis

Diagnostic Tests

- Serology: autoantibodies, antiphospholipid antibodies, complement; inflammatory markers: C-reactive protein, erythrocyte sedimentation rate; blood chemistries; complete blood count; urinalysis; lumbar puncture; renal biopsy

Lupus nephritis is present at the time of SLE diagnosis in about 25% to 50% of adult patients and 60% of patients develop it during the disease course. It is more common in African American, Hispanic, and Asian patients than in White patients and more prevalent in men than in women. It is also more common in those with juvenile-onset SLE than those with adult-onset lupus.[32] The International Society of Nephrology/Renal Pathology Society devised a classification system for lupus nephritis based on histologic findings: Class I: minimal mesangial; Class II: mesangial proliferative; Class III: focal (less than 50% of glomeruli involved); Class IV: diffuse (50% or more of glomeruli involved); Class V: membranous; and Class VI: advanced sclerosing (at least 90% globally sclerosed glomeruli without residual activity). Patients with nephritis may also have hypertension and accelerated atherosclerosis.[32]

The central, peripheral, and autonomic nervous systems can be involved in SLE. The prevalence of this involvement is around 56.3% with 93.1% CNS and 6.9% peripheral, but depends on the population studied and methods for detecting the involvement.[33] About 50% of neuropsychiatric events appear within the first 3 to 5 years after the onset of SLE. Events can be categorized as ischemic, involving antiphospholipid antibodies, thrombosis, and immune complexes. These are often focal. Others result from an autoimmune-mediated neuroinflammatory pathway and are more likely diffuse in their manifestations. Only about one-third of neuropsychiatric events can be attributed to SLE.[33] Mild nonspecific neuropsychiatric findings such as headache, mood disorders, anxiety, and mild cognitive dysfunction are very common in SLE and are sometimes excluded in estimating prevalence. Findings more indicative of neuropsychiatric lupus include cerebrovascular disease (ischemic stroke and/or transient ischemic attack) and seizures; severe cognitive dysfunction, acute confusional state, peripheral neuropathy, and psychosis; and less commonly chorea, movement disorders, cranial nerve neuropathies, and aseptic meningitis.[33,34] Risk factors include general SLE disease activity, prior neuropsychiatric events, and presence of antiphospholipid antibodies. It is important to assess contributing factors and to rule out other possible etiologies of these manifestations such as medication use, infection, and metabolic abnormalities. The diagnostic approach will vary depending on the clinical presentation and preliminary findings, but can include a thorough history and physical, lumbar puncture with cerebrospinal fluid analysis (mostly to exclude infection), electroencephalogram, serology, complete blood count, blood chemistries, neuropsychological assessment of cognitive function, nerve conduction studies, and magnetic resonance imaging. An attribution algorithm to determine the likelihood of neuropsychiatric SLE was developed by a study group of the Italian Society of Rheumatology. It scores on timing with respect to SLE onset, nonspecific events, confounding factors, and favoring factors.[34]

Cardiovascular disease is a leading cause of death in patients with SLE.[3] Patients with SLE can not only present with pericarditis, myocarditis, and pulmonary arterial hypertension, but they are also at increased risk for accelerated atherosclerosis.[13,32] This is probably related to the chronic inflammation associated with the disease and adverse drug reactions of the drugs (eg, high-dose corticosteroids) used to treat it. Antiphospholipid antibodies and type I interferons may play a role in the pathogenesis.

Hematologic manifestations are often associated with SLE. Autoimmune cytopenias such as thrombocytopenia, leukocytopenia, and hemolytic anemia may be observed.[13]

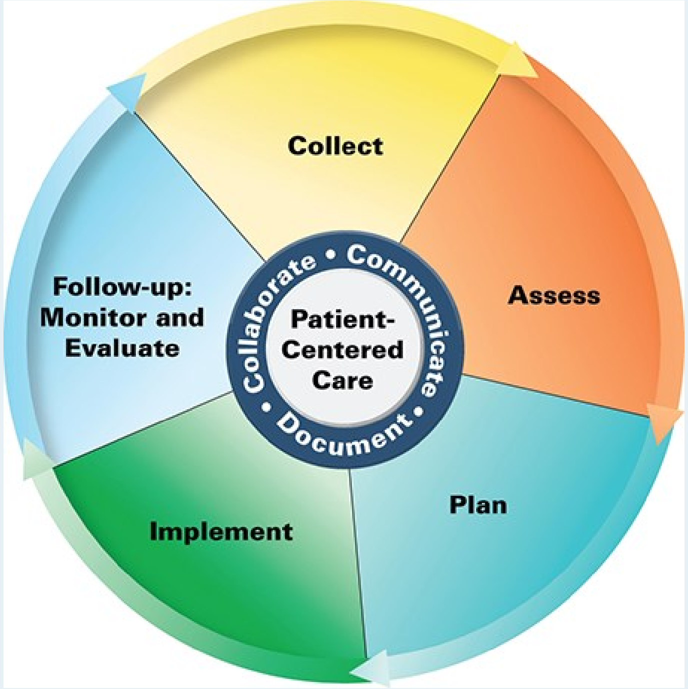
TREATMENT

Desired Outcomes

The goal of therapy should be identified. Ideally, the goal should be remission, but complete remission with the absence of clinical activity and no use of glucocorticoids or immunosuppressive therapy is rare. Achieving low disease activity based on assessment scores with use of antimalarials, prednisone doses no more than 7.5 mg, and well-tolerated immunosuppressive drugs can halt damage and prevent flares.[35] Patients should be involved in treatment decisions, taking into account their preferences, priorities, and pregnancy plans. Therapy should be designed to prevent disease flares and involvement of other organs, decrease disease activity and prevent damage, achieve and maintain remission, reduce use of corticosteroids, and improve quality of life, while minimizing adverse drug reactions and costs. Success in achieving these outcomes depends on disease severity and the type and extent of organ impairment. In general, the prognosis is better if lupus is limited to skin and musculoskeletal findings. The worst prognosis is seen with renal or CNS involvement.[32,33] Hydroxychloroquine is recommended for all patients with SLE and is the cornerstone of therapy.[35] Survival and quality of life have improved with a better understanding of disease mechanisms and new therapeutic options. Mortality is affected by SLE disease activity, cardiovascular risks, and infections.

PATIENT CARE PROCESS

Patient Care Process for Systemic Lupus Erythematosus



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, pregnancy status)
- Patient history (past medical, pregnancies and outcomes, symptoms, family, social—dietary habits, alcohol, and tobacco use)
- Current medications and prior lupus medication use
- Immunization history
- Objective data (see Clinical Presentation box and Table 107-1)
  - BP, heart rate, height, weight, and BMI; other physical examination findings
  - Labs (metabolic panel, Scr, BUN, urinalysis, CBC, ANA, antiphospholipid antibodies, direct Coombs test, other lupus-associated antibodies, complement, inflammatory markers (ESR, CRP)
  - Other diagnostic tests when indicated (eg, ECG, CXR, skin, or kidney biopsy)

Assess

- Presence of cutaneous, renal, neurologic, hematologic, cardiac, or pleural manifestations of lupus
- Evidence of antiphospholipid syndrome (thromboembolic events, miscarriages)
- Current medications that could be associated with drug-induced lupus
- Appropriateness and effectiveness of current lupus regimen (see Figs. 107-2 and 107-3)
- Psychological effects of lupus

Plan*

- Tailored lifestyle modifications (eg, diet, exercise, weight management, protection from sun, smoking cessation, keeping warm if Raynaud's phenomenon occurs)
- Drug therapy regimen including specific medications based on disease manifestations, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Figs. 107-2 and 107-3 and Tables 107-2 and 107-3)
- Monitoring parameters including efficacy (eg, skin manifestations, cardiovascular events, thromboembolic events, miscarriages, kidney health, neurologic events), safety (medication-specific adverse drug reactions), and time frame
- Patient education (eg, purpose of treatment, dietary and lifestyle modifications, drug therapy, pregnancy considerations, osteoporosis prevention if taking corticosteroids)
- Self-monitoring of skin and BP—where and how to record results
- Immunizations as needed; consider timing of live vaccines with respect to immunosuppressive drug use and pregnancy
- Referrals to other providers when appropriate (eg, physician, dietician, counselor)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence

- Schedule follow-up

Follow-up: Monitor and Evaluate

- Determine goal attainment based on disease manifestations
- Presence of adverse drug reactions
- Occurrence of cardiovascular events, infections, and development/progression of kidney or other organ impairment
- Patient adherence to treatment plan using multiple sources of information

* ***Collaborate with patient, caregivers, and other healthcare professionals.***

General Approach

Patients with SLE should be counseled about the importance of lifestyle modifications such as protection from the sun, smoking cessation, exercise, and weight control. The need for immunizations should be assessed with consideration of appropriate timing with respect to immunosuppressive drug use. The effects of disease activity and treatment on pregnancy outcomes should be discussed. Patients should be evaluated and treated for comorbidities such as hypertension, hyperlipidemia, and depression.

Treatment of SLE depends on the patient's symptoms, organ involvement, comorbidities, and other patient-specific factors. Mild symptoms can be managed with nonsteroidal anti-inflammatory drugs (NSAIDs) with or without other analgesics.[36] Antimalarial drugs have numerous beneficial effects in SLE and many experts feel that most patients with the disease should always receive one of these drugs.[35] Corticosteroids are used to treat most forms of SLE and up to 57% to 86% of patients receive continuous/chronic therapy.[37] The need for osteoporosis prevention should be assessed.[38] If the above therapy is ineffective or major organs are involved, immunosuppressive or immunomodulatory drugs are added.[36] The specific treatment is determined by the organs involved and severity of the disease (Fig. 107-2).[39] Belimumab for lupus nephritis, anifrolumab, and voclosporin are approved drugs that have not been incorporated into guidelines other than by class. Patients must be educated about the importance of adherence to treatment. Only 25% to 57% of patients with SLE are adherent to their medications and up to 33% discontinue therapy after 5 years.[40] The expected time for response to lupus medications also needs to be discussed because patients may interpret delayed onset as ineffectiveness.

FIGURE 107-2

Algorithm for the treatment of SLE. (CLE, cutaneous lupus erythematosus; CVD, cardiovascular disease; IVIG, intravenous immunoglobulin; MMF, mycophenolate mofetil; SLE, systemic lupus erythematosus.) Nonpharmacologic Therapy

⑤ Patient perceptions of well-being and quality of life are affected not only by disease activity, but also by social support, coping mechanisms, feelings of helplessness, and abnormal illness-related behaviors.[36] Good social support can improve outcomes, in part by making it easier for patients and their families to navigate the healthcare system and utilize resources.[41] Counseling and support groups may help patients' mental well-being and coping mechanisms, but do not affect SLE disease activity. Aerobic exercise may help decrease patients' risk for cardiovascular events and osteoporosis and may also improve fatigue, depression, anxiety, and sleep disturbances, which are frequently experienced in SLE.[42] Exercise can also help with weight loss. Obesity is associated with worse patient-reported outcomes including quality of life and disease activity.[43]

Since photosensitivity is common in SLE, patients should wear protective clothing and broad-brim hats and use sunscreens with UV-A and UV-B filters to protect themselves from the sun.[30] Since there is systemic absorption of sunscreen ingredients, the FDA recommends use of barrier sunscreens that contain zinc oxide or titanium dioxide as being safer.[44] Sunscreens should be applied in sufficient quantity (about 2 mg/cm^3) 20 to 30 minutes before sun exposure. People with SLE should avoid tanning salons.[30]

Patients should be counseled to stop smoking. Smoking cessation is important, not only because it decreases cardiovascular risk, but because smoking can exacerbate SLE and diminish the effectiveness of antimalarials and belimumab.[12] Smoking damages the skin, resulting in increased cutaneous lupus disease activity and worse quality of life.[14]

Pharmacologic Therapy

⑥ Treatment is personalized based on the manifestations of SLE in the patient. It consists of a combination of immunosuppression and symptomatic and supportive therapies. The only drugs approved by the FDA for treatment of SLE are aspirin, prednisone, hydroxychloroquine, belimumab, anifrolumab, and voclosporin. The use of other drugs for SLE, even those considered "standard of care," is considered "off-label" use. For many of these drugs, the optimal doses and duration of therapy for induction and maintenance of response in SLE have not been determined. Ideally, drugs should be safe, effective, and affordable.[45]

Organization or expert task force treatment recommendations have been published for lupus nephritis, neuropsychiatric lupus, and antiphospholipid antibody carriers.[6,19,46,47] An ACR committee developed guidelines for screening, treatment, and management of lupus nephritis.[6] All patients with nephritis should receive hydroxychloroquine to reduce damage and flares. An angiotensin-converting enzyme inhibitor or angiotensin receptor blocker can reduce proteinuria by about 30% in those with proteinuria of 0.5 g/day or more and delay progression of renal disease. Blood pressure should be maintained at no more than 130/80 mm Hg. Patients with low-density lipoprotein cholesterol greater than 100 mg/dL (2.59 mmol/L) should receive a statin to prevent accelerated atherosclerosis. More specific treatment is based on the type of nephritis. The first two classes, minimal mesangial and mesangial proliferative lupus nephritis do not usually need immunosuppressive therapy. Focal and diffuse lupus nephritis (Classes III and IV) are treated similarly with aggressive use of glucocorticoids and immunosuppressive therapy. Figure 107-3 shows the induction regimens for these patients and the levels of evidence to support the recommendations. White patients with Western or Southern European backgrounds respond as well to low-dose IV cyclophosphamide ("Euro-Lupus" regimen of 500 mg every 2 weeks for six doses) as to high-dose regimens (500-1,000 mg/m^2 body surface area once a month for six doses) (Level B evidence). African American and Hispanic patients respond less well to IV cyclophosphamide than do White or Asian patients. Those of African or Hispanic origin may respond better to mycophenolate mofetil than to cyclophosphamide.[32] Asian patients require lower doses of mycophenolate mofetil (Level C evidence).[6] Patients with a combination of Class V with III or IV would be treated similar to those with only III or IV. The initial cyclophosphamide or mycophenolate mofetil therapy should be continued for 6 months unless proteinuria or serum creatinine worsens by 50% or more at 3 months (Level A evidence). After 6 months of induction therapy, patients who have improved can be maintained on mycophenolate mofetil or azathioprine, with low doses of corticosteroids if needed. Patients with pure Class V, membranous lupus nephritis, and nephrotic range proteinuria of more than 3 g/day should receive induction therapy with mycophenolate mofetil 2 to 3 g/day with prednisone 0.5 mg/kg/day for 6 months (Level A evidence). Those who improve can be maintained on mycophenolate mofetil 1 to 2 g/day or azathioprine 2 mg/kg/day. Patients who do not respond should be treated with cyclophosphamide 500 to 1,000 mg/m^2/month for 6 months with IV pulse glucocorticoids, followed by prednisone 0.5 to 1 mg/kg/day.[6] Maintenance therapy should be continued for at least 3 to 5 years in complete renal remission and some experts recommend not less than 6 years since the risk of flares decreases after that. Tapering of therapy should start with glucocorticoids, followed by immunosuppressives.[47] Patients with advanced sclerosing lupus nephritis (Class VI) should be considered for renal replacement therapy.[6] EULAR/European Renal Association-European Dialysis and Transplant Association updated their guidelines for management of lupus nephritis in 2019.[47] They recommend a renal biopsy for any patient with SLE and evidence of kidney involvement such as persistent proteinuria of 0.5 g/24 hr or more or a urine protein to creatinine ratio of at least 500 mg/g in morning first void urine (Level 2b, Grade B). The overall recommendations are similar to those of the ACR with some key differences. They recommend the higher initial dose of cyclophosphamide only for patients at high risk for kidney failure. They suggest the addition of a calcineurin inhibitor (especially tacrolimus) to mycophenolate mofetil as alternative initial therapy, especially for patients with nephrotic range proteinuria or the calcineurin inhibitor as monotherapy for pure Class V nephritis. Another difference is after intravenous pulse doses of methylprednisolone (total dose 500-2,500 mg), oral prednisone should be started at a dose of 0.3 to 0.5 mg/kg/day for up to 4 weeks, then tapered to a dose of 7.5 mg/day or less by 3 to 6 months (Level 2b/C). For pure Class V, the prednisone should be started at 20 mg/day and tapered to 5 mg/day or less by 3 months (Level 2b/C).[47] Since proteinuria at 12 months is a good predictor of risk for end-stage renal disease, a goal of therapy is at least a 50% decrease in proteinuria at 6 months with less than 0.5 to 0.7 g/24 hr by 12 months. It may take longer to reach this goal if the patient initially has nephrotic-range proteinuria.[47] They noted the promising results of trials adding belimumab, voclosporin, rituximab, or obinutuzumab to standard-of-care therapy for lupus nephritis.

A task force of the European League Against Rheumatism (EULAR) developed recommendations for the management of neuropsychiatric lupus. Treatment depends on the manifestations. Symptomatic therapy (eg, anticonvulsants and antidepressants) should be given as needed. More specific treatment depends on whether the problem is determined to be inflammatory or thrombotic or both. If there is inflammation or neurotoxic damage in the presence of generalized SLE activity, glucocorticoids alone or in conjunction with immunosuppressive drugs such as azathioprine or cyclophosphamide should be given (Strong evidence). If the condition does not respond, other treatments such as plasma exchange, IV immunoglobulin, or rituximab can be tried. If the problem is related to moderate-to-high titers of antiphospholipid antibodies and/or thrombosis, anticoagulants and/or inhibitors of platelet aggregation should be used (Sufficient evidence).[46] Recommendations have not significantly changed over the years. Antimalarials may decrease the risk for seizures and brain atrophy through their anti-inflammatory and antithrombotic effects. Results of clinical trials of rituximab, belimumab, anifrolumab, and mycophenolate mofetil have been promising.[33]

Arthralgias and arthritis are common in SLE.[48] Patients often have prolonged morning stiffness and mild-to-moderate joint swelling. Treatment can include low-dose glucocorticoids and antimalarials. If these are inadequate, methotrexate can be added.[48] NSAIDs should be avoided or used with great caution because of their adverse renal effects.[47] For refractory cases, other disease-modifying antirheumatic drugs such as leflunomide, azathioprine, mycophenolate mofetil, or tacrolimus may be tried.[49] Although there is concern about drug-induced lupus with TNF-α inhibitors, successful use of etanercept for resistant lupus arthritis has been reported.[49]

The first step in the management of cutaneous lupus erythematosus is counseling patients to protect themselves from ultraviolet light and stop smoking as described above.[14] Drug treatment is personalized based on the extent and severity of involvement. Recent guidelines from EULAR, the European Dermatology Forum/European Academy of Dermatology and Venereology, and S2k recommend topical therapy as first-line treatment for cutaneous lupus.[35,50] Topical corticosteroids are commonly used, but may not provide adequate clearing of lesions when used alone.[44] The choice of corticosteroid depends on the location of application. Low-potency corticosteroids (eg, fluocinolone acetonide 0.01% and hydrocortisone acetate 1%) should be used on areas with thin skin such as the face and groin, mid-potency (eg, triamcinolone acetonide, and hydrocortisone valerate or butyrate) for trunk and extremities, and high potency (eg, clobetasol propionate and betamethasone dipropionate) for thick-skin areas such as scalp, soles, and palms. Creams or, for more severe disease, ointments, are used on the body, and foams or solutions on the scalp.[44] Intralesional triamcinolone acteonide may be considered, but should not be repeated more often than every 4 to 6 weeks.[50] To avoid the adverse drug reactions of topical corticosteroids, such as skin atrophy, telangiectasias, and steroid-induced dermatitis, the lowest effective potency and duration of therapy should be used. A common recommendation is to use topical corticosteroids for 2 weeks (not more than a few), then only on weekends for maintenance.[44] Alternatively or in addition, topical calcineurin inhibitors such as pimecrolimus or tacrolimus may be used. Other topical products that have been tried are R-salbutamol, Janus kinase inhibitors, clindamycin, and retinoids.[44] Antimalarials have photoprotective effects and are commonly used as first-line systemic therapy in the management of severe or disseminated cutaneous lupus.[50] If hydroxychloroquine alone is ineffective, quinacrine (mepacrine), if available from compounding pharmacies, may be added.[44] For refractory disease, other systemic drugs such as corticosteroids, methotrexate, mycophenolate mofetil, azathioprine, dapsone, thalidomide, lenalidomide, baricitinib, oral retinoids, or biologics (eg, rituximab, belimumab, or anifrolumab) may be added.[44] Patients should be screened for glucose-6-phosphate dehydrogenase (G6PD) deficiency before getting dapsone.[50] Vitamin D should also be considered. It has some immunomodulating effects and patients with cutaneous lupus may be vitamin D deficient because of their sun avoidance.[50] More studies are needed to support the use of these drugs in patients with cutaneous lupus. The choice of agents may be guided by other organ involvement.

Dosing information for selected drugs is given in Table 107-2. Since most of the drugs used to treat SLE are not FDA-approved for that indication, the doses given are based on other uses for those drugs. Table 107-3 lists adverse drug reactions and drug monitoring parameters. Selected issues concerning the drugs are discussed below.

TABLE 107-2

Dosing of Drugs Used to Treat Systemic Lupus Erythematosus

Drug	Brand Name	Initial or Starting Dose	Usual Range or Maintenance Dose	Special Population Doses	Comments (adverse drug reactions, special populations)
NSAIDs/salicylates	Various drugs				Caution in patients with renal insufficiency, cardiovascular disease, gastrointestinal problems
Glucocorticoids	Deltasone (prednisone), Medrol (prednisolone)	0.3-1 mg/kg/day PO	Prefer ≤5-10 mg/day PO		Dose depends on organ involvement and severity; initial dose may be given for 4-6 weeks, then tapered for maintenance; no standard dose
	Solu-Medrol (methylprednisolone)	100-1,000 mg IV daily × 3			Severe disease; later, dose tapered and changed to PO
Hydroxychloroquine	Plaquenil	400 mg PO daily or 200 mg twice daily	200-400 mg PO daily	Dosing adjustment may be needed with renal or hepatic dysfunction	Dose should not exceed 5 mg/kg/day actual weight to minimize retinopathy risk
Belimumab	Benlysta	10 mg/kg IV every 2 weeks × 3 or	10 mg/kg IV every 4 weeks or	No adjustment for hepatic impairment; no adjustment for renal impairment if CrCl ≥15 mL/min (0.25 mL/s); no studies in pregnant or breastfeeding women	IV infusion over 1 hour; consider premedication to prevent infusion and hypersensitivity reactions; observe for infusion reaction after first two infusions
		SLE: 200 mg SC weekly	200 mg SC weekly		

		Lupus nephritis:400 mg SC weekly x 4			
Voclosporin	Lupkynis	23.7 mg PO every 12 hours	23.7 mg PO every 12 hours	Dose adjustment for renal or hepatic impairment	Do not use if baseline BP >165/105 mm Hg or baseline eGFR ≤45 mL/min/1.73 m^2
Anifrolumab-fnia	Saphnelo	300 mg IV every 4 weeks	300 mg IV every 4 weeks		IV infusion over 30 minutes; risk of hypersensitivity and infusion reactions
Cyclophosphamide	Cytoxan	500-1,000 mg/m^2 BSA IV every month × 6 or 500 mg IV every 2 weeks × 6		Dosing adjustment might be needed with renal dysfunction; low and high doses may have equivalent efficacy in White patients with European background	Infertility in women and men, teratogenicity of concern
Mycophenolate mofetil	Cellcept	2-3 g/day PO divided into 2-3 doses for 6 months	0.5-3 g/day PO	Lower doses may be needed in Asian patients (1.5-2 g/day) than non-Asian patients; may be more effective than cyclophosphamide in Black and Hispanic patients	Contraindicated in pregnancy
	Myfortic (enteric coated mycophenolate sodium)				
Azathioprine	Imuran	2 mg/kg/day PO	1.5-2 mg/kg/day PO	Pregnant patients ≤2 mg/kg/day	Lower dose if thiopurine methyltransferase (TPMT) deficient
Methotrexate	Trexall, Otrexup, Rasuvo, RediTrex, Xatmep	5-15 mg PO or SC weekly	15-25 mg PO or SC weekly		Decrease toxicity by giving with folic acid
					Avoid use in elderly or if GFR <30 mL/min (0.5 mL/s)
Rituximab	Rituxan	375 mg/m^2 BSA IV weekly × 4 or 500-1,000 mg IV on days 1 and 15		Variable doses have been used	Alternative for patients refractory to other treatments; may be more effective in Black patients

BSA, body surface area; CrCl, creatinine clearance; IV, intravenously; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, orally.

TABLE 107-3

Monitoring of Drugs Used to Treat Systemic Lupus Erythematosus

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
NSAIDs/salicylates	Gastrointestinal bleeding, hepatic toxicity, renal toxicity, hypertension, cardiovascular events, aseptic meningitis	CBC[a], platelets[a], creatinine[a], urinalysis, AST/ALT[a], blood pressure[a]	Antihypertensive effects of calcium channel blockers affected less than other classes
Glucocorticoids, systemic	Osteoporosis, cataracts, glaucoma, hyperglycemia/diabetes, hypertension, dyslipidemia, thinning of the skin, weight gain, fat redistribution, sleep/mood disturbances	Blood pressure[a], serum glucose[a], lipid panel[a], bone densitometry, ophthalmic examinations	Patients should receive osteoporosis preventive therapy; high doses of systemic corticosteroids are associated with infections, myopathy, psychological disturbances, osteonecrosis, and stroke
Glucocorticoids, topical	Skin atrophy, telangiectasias, dermatitis	Skin appearance	Avoid prolonged use, especially of high-potency steroids
Hydroxychloroquine	Retinal toxicity, gastric intolerance, rash, skin hyperpigmentation	Funduscopic and automated visual field examinations, consider spectral domain optical coherence tomography, multifocal electroretinogram, or fundus autofluorescence (frequency depends on risk), CBC, AST/ALT, albumin, chemistry panel, creatinine	Risk for retinal toxicity increased with doses >5 mg/kg/day actual body weight, more than 5 years therapy, renal or macular disease, or concurrent tamoxifen use
Belimumab	Infusion reactions, hypersensitivity, nausea, diarrhea, fever, nasopharyngitis, bronchitis, insomnia, pain in extremity, depression, migraine	Monitor for serious infections, hypersensitivity/infusion reactions, worsening depression, mood changes, or suicidal thoughts	No live vaccines 30 days before or during belimumab therapy; consider premedication with antipyretic and antihistamine
Voclosporin	Infections, lymphomas, other malignancies; QT interval increase, hyperkalemia, neurotoxicity	Monitor for infections, BP, eGFR, potassium, electrocardiogram	Limit sun exposure; reduce dose if given with CYP3A4 inhibitors
Anifrolumab-fnia	Upper respiratory tract infections, nasopharyngitis, herpes zoster, anaphylaxis, angioedema	Monitor for infections	Insufficient data on use during pregnancy or lactation
Cyclophosphamide	Myelosuppression, opportunistic infections, hemorrhagic cystitis, bladder malignancy, infertility	CBC[a], platelets[a], creatinine, AST/ALT, urinalysis[a], urine cytology[a], PAP test[a]	Greater risk for cystitis with oral form than IV; decrease with hydration and mesna
Mycophenolate mofetil	Myelosuppression, nausea, vomiting, diarrhea	CBC[b], platelets[b], creatinine, chemistry panel, AST/ALT, chest x-ray	Gastrointestinal side effects may limit use and compliance; these symptoms

			may be less with an enteric-coated form
Azathioprine	Myelosuppression, hepatotoxicity	CBC[c,d], platelets[c,d], creatinine[d], AST/ALT[c,e], chemistry panel[d], albumin, TPMT assay, PAP test	Test thiopurine methyltransferase (TPMT) before starting; toxicity greatly increased if deficient
Methotrexate	Hepatic, hematologic, pulmonary toxicity, stomatitis	CBC[c,f], platelets[c,f], creatinine[c,f], AST/ALT[c,f], albumin[c,f], bilirubin, chemistry panel[g], alkaline phosphatase[b], chest x-ray	Check hepatitis B and C serologies before starting if at risk
Rituximab	Infusion reactions, infections, neutropenia, mucocutaneous reactions, fever, fatigue, progressive multifocal leukoencephalopathy	CBC[h], platelets[h], creatinine, vital signs, human antichimeric antibody (HACA) titers	Consider pretreatment with acetaminophen, diphenhydramine, corticosteroid to decrease infusion reactions

[a] 52 weeks

[b] 4 weeks

[c] 12 weeks

[d] Every 1-2 weeks after dose change

Monitoring parameters should be checked at baseline and at interval noted:

[e] 26 weeks

[f] Every 2 weeks after dose change

[g] 2-4 weeks during 3 months after dose change

[h] 8 weeks

[i] 8-16 weeks

Data from References 51,52,68,98.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are used as first-line treatment for arthritis, musculoskeletal complaints, fever, and serositis.[39] They are not disease-modifying, but are used to relieve symptoms.[51] Low-dose aspirin is used in patients with antiphospholipid antibodies.[19] One concern with NSAIDs is that they can decrease renal function which can complicate evaluation of lupus nephritis. They have the potential to increase cardiac events in patients who already are at elevated risk. Other adverse drug reactions include hepatotoxicity, gastrointestinal (GI) bleeding, and aseptic meningitis.[39]

Corticosteroids

Corticosteroids, as monotherapy or as adjuncts to other treatments, can control flares and maintain low disease activity in SLE. Their effects have a rapid onset, whereas other therapies may take months or over a year to achieve their maximum benefits. The corticosteroids can be used topically or systemically.

Although corticosteroids have been used to manage SLE since the 1950s, optimal doses, duration of therapy, and tapering regimens have not been determined. High doses given in a pulse IV administration regimen are generally free of serious adverse drug reactions and rapidly produce strong immunomodulatory effects. They are used to treat flares and quickly reduce inflammation. Doses should slowly be tapered down to the lowest effective dose.[52] Corticosteroids are the foundation for treatment of most forms of SLE, but high-dose oral corticosteroid use is associated with increased lupus organ damage accrual, infection, and death. Oral maintenance doses should be kept as low as possible with pulse methylprednisolone doses used for disease flares and in combination with other drugs that are steroid-sparing.[52]

Common adverse drug reactions of low(prednisone less than 7.5 mg/day)-to-moderate (7.5-30 mg/day) doses are shown in Table 107-3. Although higher doses may be divided, single morning doses may be associated with fewer adverse drug reactions and less adrenal suppression. Chronic use of any dose is associated with cardiovascular complications, psychological disturbances, glaucoma, cataracts, hyperglycemia, weight gain, avascular necrosis of bone, and osteoporosis.[37] Corticosteroids decrease absorption of vitamin D and increase catabolism of 25(OH) vitamin D and 1,25$(OH)_2$ vitamin D. According to the 2017 ACR guideline for the prevention and treatment of glucocorticoid-induced osteoporosis, all patients taking prednisone at a dose of 2.5 mg daily or more for at least 3 months should optimize calcium and vitamin D intake in addition to lifestyle changes such as balanced diet, maintenance of recommended weight, smoking cessation, and limiting alcohol intake. Additional treatment is based on Fracture Risk Assessment Tool (FRAX) score (Conditional recommendation-limited data).[38] To avoid adrenal insufficiency, patients on chronic corticosteroid therapy should not have treatment stopped abruptly. Some clinicians will increase doses during times of stress such as surgery because of concerns regarding adrenal insufficiency and hypotension, but this can increase the risk of hyperglycemia, postoperative infections, and impaired wound healing. These supraphysiologic doses may not be necessary for minor/intermediate intensity surgeries such as joint arthroplasty in adults taking less than 20 mg/day prednisone.[53] For major surgeries, patients may be given hydrocortisone 50 mg IV intraoperatively and every 8 hours after surgery until the patient's usual oral dose can be resumed.[54] Prolonged use of topical corticosteroids can lead to atrophy of the skin and telangiectasias (small dilated blood vessels).[44]

Antimalarials

The antimalarials, such as chloroquine and hydroxychloroquine, have long been used in rheumatology practice. Hydroxychloroquine has fewer adverse reactions and is the preferred drug. In the past, hydroxychloroquine was primarily used for skin and joint manifestations of SLE, but most experts believe that all patients, including pregnant and lactating women, with SLE should receive hydroxychloroquine. There is high-quality evidence that shows it prevents lupus flares and improves long-term survival; moderate-quality evidence that it protects against bone mass loss, and has protective effects against thrombosis and irreversible organ damage.[55] It has a beneficial effect on lipids and fasting blood glucose, decreases the risk of thrombosis in patients with antiphospholipid antibodies, and decreases infections. It can allow corticosteroid doses to be decreased.[52] When given to patients with some findings consistent with SLE, it can delay the time for them to fully meet criteria for the disease. Patients receiving hydroxychloroquine often have disease flares when the drug is discontinued.[56]

Hydroxychloroquine has anti-inflammatory, immunomodulatory, and antithrombotic effects. It reduces concentrations of inflammatory cytokines such as interleukins 1, 2, 6, 17, and 22, interferon alpha and gamma, and TNF-α. It alters antigen presentation and T-cell proliferative responses. Its key activity may be decreasing activation of toll-like receptors, which are important in innate immunity and autoimmune diseases. It reduces platelet aggregation and thrombosis.[56] Finally, it may reduce cardiovascular risk factors such as hyperlipidemia and diabetes mellitus and improve survival.[52] The LUMINA (LUpus in MInorities, NAture vs nurture) multiethnic study found that hydroxychloroquine has a protective effect on survival. It may delay the development of renal damage and the occurrence of integument damage (severe skin damage including scarring, ulcers, and scarring alopecia).[55,56]

Although some studies showed reduced disease activity and flares with hydroxychloroquine whole blood concentrations over 1,000 ng/mL (μg/L; 2,980 nmol/L), other studies where doses were adjusted to achieve that concentration did not show better disease control. Studies of cutaneous lupus showed good improvement at 750 ng/mL (μg/L; 2230 nmol/L), while others considered 500 ng/mL (μg/L; 1490 nmol/L) to be the minimum therapeutic concentration. Hydroxychloroquine concentration monitoring be used as a measure of adherence to therapy.[57] The drug is primarily eliminated by the kidneys and has a long tissue half-life of about 40 to 50 days. Low concentrations may therefore be an indicator of consistent nonadherence or abnormal metabolism.[57] It may take 2 to 8 weeks to see the therapeutic effects of hydroxychloroquine and up to 3 to 6 months for maximum clinical efficacy.[57]

Adverse drug reactions with hydroxychloroquine are usually mild. Most common are GI and skin reactions and they usually improve with dose reduction.[56] Prolongation of the QT interval on electrocardiograms is rare at the doses used for SLE.[52] The main concern is retinal toxicity, but the incidence is low and may be less than that seen with chloroquine. The cumulative risk depends on the duration of therapy and is less than 1% in patients receiving the drug at recommended doses for 5 years, less than 2% up to 10 years, and less than 5% after 20 years.[58] Major risk factors are the duration of use over 5 years, daily doses more than 5 mg/kg actual body weight, concurrent use of tamoxifen, or preexisting kidney dysfunction or macular disease. Advanced retinal damage has a characteristic bull's-eye appearance on funduscopic examination and is irreversible, but this should not be seen with appropriate monitoring. Patterns of damage are different in East Asian patients. Early recognition of damage may minimize vision loss. The current ACR/American Academy of Dermatology/American Academy of Ophthalmology 2020 monitoring recommendations are to have baseline screening tests within the first few months, including retinal examination with optical coherence tomography and automated visual fields. After 5 years, patients should begin annual examinations unless the patient is considered to be at high risk, in which case yearly testing would begin earlier. If there are suspicious findings, other tests such as multifocal electroretinogram and fundus autofluorescence should be performed. If toxicity is suspected, the drug should be discontinued or the patient counseled about risks of blindness versus disease flares.[58]

Biologic Agents

Since autoantibody formation is an important feature of SLE, B-cells are a logical target for SLE therapy. B-lymphocyte stimulator (BLyS) is a cytokine that is important for B-cell survival, maturation, and differentiation. Belimumab is a fully human IgG1-λ monoclonal antibody that binds to soluble BLyS, which prevents BLyS from binding to receptors on B-cells and promotes apoptosis of B-lymphocytes. Belimumab is FDA-approved for treatment of autoantibody-positive active SLE in addition to standard therapy. It was the first drug approved by the FDA in over 50 years for management of SLE.[21] Approval of intravenous belimumab was based on two international phase III trials: BLISS-76, conducted primarily in Europe and North America, and BLISS-52, which was carried out in Eastern Europe, South America, and the Asia-Pacific region. These trials had strict entry criteria and used the new SLE Responder Index (SRI) assessment criteria. For both studies, the primary efficacy endpoint was the SRI at 52 weeks. Entry requirements included positive ANA or anti-dsDNA, and active SLE (SELENA-SLEDAI [measure of disease activity] score of 6 or greater) while receiving standard treatment (prednisone, NSAIDs, antimalarials, and/or immunosuppressive drugs [but not IV cyclophosphamide or other biologics]). Patients had to be on stable therapy for at least 30 days. The most common organ systems involved were musculoskeletal and mucocutaneous. Patients with severe active lupus nephritis or CNS lupus were excluded. Patients received belimumab 1 mg/kg, 10 mg/kg, or placebo by IV infusion every 2 weeks for two doses, then every 4 weeks, in addition to their standard therapy. There were restrictions on concomitant medications, and those became stricter as the studies progressed. The response rate was significantly higher in the group receiving belimumab 10 mg/kg as compared to placebo in both studies. Patients receiving belimumab also had greater improvement in health-related quality of life and fatigue. Patients of African descent did not benefit from belimumab.[21] However, later studies such as the EMBRACE trial, reported favorable responses to belimumab in all racial and ethnic groups.[21,59] Open-label trials showed extended benefit to 10 years. The 52-week BLISS-SC trial showed the safety and efficacy of subcutaneously administered belimumab and patients preferred the convenience of self-administration.[21] Belimumab was approved by the FDA for treatment of lupus nephritis based on the two-year BLISS-LN study. This international double-blind study compared belimumab to placebo added to standard therapy. Significantly more patients in the belimumab group achieved the primary efficacy renal response of urinary protein to creatinine ratio of 0.7 or less, an eGFR no worse than 20% below the pre-flare value or an eGFR of at least 60 mL/min/1.73 m^2, and no rescue therapy use.[60]

Rituximab is a chimeric monoclonal antibody directed at the CD20 antigen on B-cells.[61] Although many case reports and open-label trials have reported beneficial effects of rituximab in SLE, randomized, placebo-controlled trials of rituximab have not demonstrated efficacy in SLE. The largest of these trials was the EXPLORER (Efficacy and Safety of Rituximab in Moderately-to-Severely Active Systemic Lupus Erythematosus) trial, which evaluated patients with extrarenal involvement treated with rituximab and immunosuppressive drugs and the LUNAR (LUpus Nephritis Assessment with Rituximab) trial that examined use of rituximab with mycophenolate mofetil and corticosteroids in patients with lupus nephritis.[61] The negative trial results could be related to the short duration of the trials, overuse of corticosteroids, high background immunosuppressive regimens, or the choice of endpoints.[45] Further improvement was observed in the second year of therapy. Exploratory analyses of specific patient subgroups or different response criteria suggested some benefit. In a small study of rituximab given shortly after diagnosis, followed by mycophenolate mofetil and hydroxychloroquine, about 90% of the patients with lupus nephritis achieved a complete or partial remission without oral corticosteroids.[45] It may serve as an alternative therapy in refractory lupus nephritis, severe hematological lupus, and some CNS manifestations of the disease and is included in some guidelines.[33,45] It may also prove useful for maintenance therapy, as a steroid-sparing agent, or when preservation of fertility is desired.[61]

Other drugs targeting B-cells are being investigated in SLE. Examples of these are other anti-CD20 monoclonal antibodies such as ofatumumab, ocrelizumab, and obinutuzumab.[45] Other biologic agents have been tried in SLE with varying degrees of success, often failing in large phase III clinical trials.[45] In general, biologic drugs should not be combined. However, depletion of B-cells is associated with an increase in BAFF/BLyS and some ongoing trials use rituximab in sequence or together with belimumab to treat SLE.[45]

Anifrolumab is a fully human IgG1κ monoclonal antibody that targets type I interferons through binding the type I interferon receptor subunit 1.[51] It was studied in the MUSE, TULIP-1, and TULIP-2 trials. Patients had moderate-to-severe SLE while taking one or more standard therapies including oral corticosteroids, antimalarials, and immunosuppressives. Those with severe lupus nephritis or neuropsychiatric lupus were excluded. Most of the subjects had active skin and joint disease. After the SRI endpoint was not reached in TULIP-1, the protocol for TULIP-2 was changed to use a new endpoint – BICLA, a composite of BILAG, SLEDAI-2K, and Physician's Global Assessment. Anifrolumab decreased flares and disease activity by week 8 to 12 and was steroid-sparing. Severe skin disease improved by CLASI scores. Patients with overexpression of type I interferon-regulated genes (high interferon gene signature) may respond better to anifrolumab.[51]

As discussed later, TNF-α inhibitors may induce lupus. However, good results have been observed with etanercept as long-term treatment of refractory lupus arthritis.[49]

Immunosuppressive Drugs

Cyclophosphamide has long been used to treat severe or refractory organ involvement in SLE such as lupus nephritis, neuropsychiatric lupus, vasculitis, and hematologic disease.[52] Its role in therapy is being redefined because of the availability of newer drugs, as discussed elsewhere in this chapter. Response rate and dosing requirements may vary with patient race.[52]

Cyclophosphamide is an alkylating agent that causes cross-linkage of DNA and inhibits B- and T-cell proliferation and antibody production.[48] The drug can potentially cause hemorrhagic cystitis and bladder cancer due to acrolein, a metabolite of the drug that concentrates in the bladder.[62] The risk is greater with oral administration, higher cumulative doses, and in smokers. Intermittent pulse IV doses, hydration, and frequent voiding may decrease the risk of these adverse drug reactions. With oral administration, patients are advised to take the drug in the morning and to drink fluids for several hours. Adherence is not good with this regimen. With IV administration, IV fluids are begun before administration of the cyclophosphamide and continued for several hours after. Patients are encouraged to maintain oral hydration for 72 hours. Another method to decrease bladder toxicity is to give sodium-2-mercaptoethane sulfonate (mesna), which binds acrolein and prevents its harmful effects on the bladder. Although mesna is sometimes used with high-dose cyclophosphamide, it is only FDA-approved for use with ifosfamide. Mesna used with daily oral cyclophosphamide is expensive and inconvenient based on available dosage forms. The recommended mesna regimen with IV pulse doses of cyclophosphamide is to give IV doses, each equivalent to 20% of the cyclophosphamide dose, 15 to 30 minutes before the cyclophosphamide, then 4 and 8 hours after. Since oral mesna is about 50% bioavailable, the 4- and 8-hour mesna doses after cyclophosphamide may be given orally, each in doses equivalent to 40% of the administered dose of cyclophosphamide.[62] In practice, a variety of mesna regimens are used. The effectiveness of mesna for uroprotection in patients receiving cyclophosphamide for rheumatologic diseases has been questioned.

Mycophenolic acid (MPA) reversibly inhibits the enzyme inosine 5-monophosphate dehydrogenase (IMPDH), which is important for de novo synthesis of purine (guanosine) nucleotides. This inhibits lymphocyte proliferation, chemotaxis, and antibody production. Genetic polymorphisms of the IMPDH proteins may influence the effects of MPA, but routine testing is not recommended at this time.[47] The drug also has other immunomodulating effects such as induction of activated T-cell apoptosis, inhibition of adhesion molecule expression, and fibroblast proliferation.[48]

Mycophenolate mofetil is about 94% absorbed and is hydrolyzed to MPA, its active form. MPA is bound to albumin, so unbound drug concentrations can be affected by changes in albumin. MPA is glucuronidated in the liver to an inactive metabolite, mycophenolic glucuronide. The metabolite is excreted in the urine but also undergoes enterohepatic recycling, with conversion back to the active form. Some studies have reported better lupus nephritis response with higher trough MPA concentrations or 12-hour MPA areas under the curve, but optimal values have not been determined and these did not correlate with toxicity, so measurement is not common practice.[57] Larger trials may support the benefits of individualized dosing based on therapeutic drug monitoring.[32]

Mycophenolate mofetil has been extensively studied in the treatment of lupus nephritis. It is at least as effective as cyclophosphamide for induction therapy and as effective as azathioprine for maintenance treatment.[32] The Aspreva Lupus Management Study (ALMS) was an international study of lupus nephritis. The 6-month induction phase showed mycophenolate mofetil to be equivalent in efficacy in White and Asian patients to monthly IV pulse doses of cyclophosphamide.[32] Black and Hispanic patients responded better to mycophenolate. The response to therapy at 6 months correlated with the baseline complement C4 concentration, time since diagnosis of lupus nephritis, and eGFR. Normalization of complement C3 and/or C4 and reduction in proteinuria of at least 25% at 8 weeks also predicted renal improvement at 6 months.[63] Responders at 6 months entered a 36-month maintenance phase in which mycophenolate mofetil was superior to azathioprine in maintaining renal response and preventing disease relapse. Although adverse drug reactions occurred in more than 97% of patients in both groups, more patients receiving azathioprine withdrew from the study due to adverse drug reactions than those receiving mycophenolate mofetil.[64] The MAINTAIN trial did not find a difference in the rate of renal flare with mycophenolate mofetil compared to azathioprine 5 and 10 years after induction with low-dose IV cyclophosphamide. The difference in these results compared to the ALMS trial may be related to the difference in induction therapy, selection of patients for the maintenance phase, and in populations studied. The MAINTAIN trial studied predominantly (83%) White European patients, whereas the larger ALMS trial included a more racially diverse population (56% non-Caucasian patients). The MAINTAIN trial did find a correlation between achieving a proteinuria value of less than 0.5 g/day at 12 months and good long-term renal outcome.[65] Mycophenolate mofetil is preferred for maintenance therapy if it is used for induction.[47]

Mycophenolate mofetil may also be useful for nonrenal manifestations of SLE such as cutaneous lupus, hemolytic anemia, thrombocytopenia, vasculitis, and musculoskeletal and neuropsychiatric diseases, and can be steroid sparing.[52]

The most common adverse drug reactions with mycophenolate mofetil are gastrointestinal complaints and infections.[52] These may be severe enough to require discontinuation of therapy. The adverse drug reactions may be managed with a reduction in dose.[48] Use of an enteric-coated form of mycophenolate sodium may decrease gastrointestinal symptoms. Hematologic effects ranging from cytopenias to red cell aplasia may also be seen. Teratogenicity has been reported with mycophenolate mofetil and it is contraindicated in pregnancy.[66]

Azathioprine is a purine analog that is metabolized to mercaptopurine. It inhibits nucleic acid synthesis and affects cellular and humoral immune functions.[39,67] Mercaptopurine is inactivated by thiopurine methyltransferase (TPMT). Patients should have TPMT testing before receiving azathioprine.[65] If the activity of that enzyme is low, patients may experience more severe toxicity. Myelosuppression and gastrointestinal adverse effects correlate with TPMT polymorphism, but hepatotoxicity may not. Other metabolic pathways are also involved in the elimination of azathioprine.[67] The metabolism of azathioprine and mercaptopurine is inhibited by allopurinol and febuxostat. If the combination of these drugs is to be used, a reduction in azathioprine dose is required.[68] Azathioprine is less effective than cyclophosphamide for induction therapy in lupus nephritis, but it can be an alternative to mycophenolate mofetil for maintenance treatment.[32] Azathioprine may also be used for SLE-related arthritis, serositis, and mucocutaneous manifestations. It has steroid-sparing effects, allowing the use of lower doses of corticosteroids.[39]

Methotrexate is an inhibitor of dihydrofolate reductase, which is needed for DNA synthesis and cell proliferation.[36] Its toxicities are reduced by folic acid administration. It is dosed once weekly in the management of SLE. It is used for musculoskeletal, skin, and serosal disease and as a steroid-sparing drug.[52]

Calcineurin is a serine-threonine phosphatase that stimulates hyperactivation of T-cells, resulting in cytokine release and costimulation of B-cells with release of autoantibodies. Calcineurin also adversely affects podocytes which are important for maintaining the glomerular filtration barrier in the kidneys. Calcineurin inhibitors decrease inflammation and proteinuria.[2] Voclosporin, a calcineurin inhibitor, was the first oral drug approved by the FDA for the treatment of active lupus nephritis. Voclosporin is an analog of cyclosporine with much higher immunosuppressive effect. Voclosporin is used in combination with mycophenolate mofetil and corticosteroids. Approval was based on the randomized double-blind AURORA 1 trial that compared voclosporin to placebo added to mycophenolate mofetil and rapidly tapered oral corticosteroids in patients with active class III to V lupus nephritis. The primary endpoint was complete renal response defined as urinary protein to creatinine ratio of 0.5 mg/mg or less, with an eGFR of at least 60 mL/min/1.73 m^2 (or no decrease from baseline of more than 20%), use of no more than 10 mg prednisone equivalent per day, and no rescue medication at 52 weeks. This response was achieved in 40.8% of those receiving voclosporin compared to 22.5% on placebo.[69] The interim analysis for Aurora 2, a 104-week extension study of AURORA 1, showed that patients receiving voclosporin maintained reductions in proteinuria with no change in mean eGFR at 30 months of treatment.[70]

Other calcineurin inhibitors have also been used to treat lupus nephritis and may be a treatment option for women who are pregnant or breastfeeding.[2] Tacrolimus has a different structure with higher immunosuppressive effects and less nephrotoxicity than cyclosporine. Most of the tacrolimus studies have been conducted in Asian populations. It has been used as monotherapy for induction and maintenance therapy. It has also been used in combination with mycophenolate mofetil for induction therapy for patients with nephrotic range proteinuria.[2] The most recent European recommendations for treatment of lupus nephritis include a calcineurin inhibitor (especially tacrolimus) as alternative monotherapy for class V nephritis (Level 2b/B) or in combination with mycophenolate for patients with nephrotic range proteinuria (Level 1b/B).[47]

Janus-kinase inhibitors such as tofacitinib and baricitinib are being studied for musculoskeletal and cutaneous lupus with some success.[45] Numerous other immunosuppressive drugs have been used in SLE, especially in patients who have contraindications to the agents already discussed or who cannot tolerate them, or those whose disease is refractory to conventional treatment.

Alternative Treatments

Patients receiving conventional treatment for SLE frequently feel they have unmet needs. Often these are psychosocial and may include anxiety or depression. These needs can lead patients to try alternative therapies. Clinicians should have an open dialogue with patients about these therapies so that patients will report them. This allows practitioners to monitor for interactions with other treatments and to guide patients to therapies with greater potential for benefit and less for harm.[71]

Complementary and alternative medicine includes health systems, products, and practices that are outside the realm of conventional medicine. In general, these have not been evaluated in randomized controlled trials involving SLE patients.[71]

Concentrations of dehydroepiandrosterone (DHEA), a weak adrenal androgen, are typically decreased in SLE. DHEA supplementation may offer some limited benefit for patients' assessment of disease activity, steroid effects on bone mineral density, and time to flares in SLE.[71] Effects on oral ulcers and alopecia have also been studied.[72]

Vitamin D concentrations are decreased in SLE, especially in patients with high disease activity and those with darker skin pigmentation (eg, African American patients). A contributing factor to the deficiency is that patients are instructed to protect themselves from sunlight because of the photosensitivity that accompanies SLE.[73] Another factor may be polymorphisms in the gene involved in vitamin D degradation. Vitamin D deficiency is associated with high concentrations of inflammatory cytokines. Deficiencies not only affect bone health, but low vitamin D concentrations may also be associated with greater SLE disease activity, insulin resistance, and fatigue.[74] Low concentrations also correlate with increased cardiovascular risk factors such as hypertension and hyperlipidemia. B- and T-lymphocytes, dendritic cells, macrophages, and neutrophils have vitamin D receptors, which suggests a role for vitamin D in both innate and adaptive immune processes.[74] Baseline 25(OH) vitamin D concentrations should be checked with a current goal of at least 30 ng/mL (75 nmol/L).[50] Some suggest a daily intake of vitamin D3 of 30 to 50 μg (1,000-2,000 IU). This is especially important for patients taking corticosteroids.

Special Populations

Pregnancy and Contraception

⑦ Pregnancy planning with assessment of risk factors is key for achieving good outcomes for women with SLE and healthy babies. ACR issued recommendations for reproductive health in patients with rheumatic and musculoskeletal diseases.[75] The guideline summarizes information about pregnancy, contraception, assisted reproductive technologies, fertility preservation, hormone replacement therapy, breastfeeding, and use of medications. It distinguishes SLE with and without antiphospholipid antibodies in its recommendations. Timing of pregnancies with respect to disease activity and potential use of teratogenic medications makes contraception counseling very important. Women should be educated about fertility issues related to age and effects of medications. Cyclophosphamide therapy is associated with ovarian insufficiency, although the low-dose regimen may have minimal impact on ovarian reserve.[52] This is especially of concern in older women who wish to conceive. Estrogen-containing oral contraceptives or hormone replacement therapy are associated with SLE flares and with thrombosis, especially in women with antiphospholipid antibodies or other risk factors. The risk of flares is low in patients with stable disease.[76] Combined estrogen-progestin pill or vaginal ring or progestin-only oral contraceptives or intrauterine devices (IUDs) can be offered to women whose SLE is inactive or stable active and who do not have antiphospholipid antibodies (low-moderate strength of evidence).[75] Short-term use of hormone replacement therapy may be considered for women with severe menopausal symptoms who have stable/inactive disease and do not have antiphospholipid antibodies (moderate evidence). Copper or progestin IUDs and progestin implants are considered to be highly effective and may be better choices for contraception in patients with SLE. Since mycophenolate can reduce the effectiveness of oral contraceptives, IUDs or two other forms of contraception are recommended for patients taking that drug. The IUDs or progestin-only pills are recommended for those with antiphospholipid antibodies. Progestin-only pills are considered effective and are an alternative for those who do not want an IUD. The copper IUD may increase menstrual bleeding and cramping after insertion. However, these symptoms decrease with the progestin IUD, which may be a consideration for patients receiving anticoagulants.

Pregnancy during SLE is considered to be high risk. The risk of maternal mortality, cesarean delivery, preterm labor, lupus nephritis flares, gestational diabetes, preeclampsia, Hemolysis with Elevated Liver tests and Low Platelets (HELLP) and the risk of thrombotic, infectious, and hematologic complications are increased.[36,66,77] Fetal risks include fetal loss, preterm birth, preterm premature rupture of membranes, and intrauterine growth restriction.[66] Preeclampsia occurs in 13% to 35% of women with SLE[66] and is defined as hypertension and proteinuria (greater than 300 mg/24 hr) that develop for the first time after 20 weeks of gestation.[78] This can be difficult to distinguish from lupus nephritis. The risk for preterm preeclampsia is decreased with daily use of low-dose aspirin begun before 16 weeks gestation.[66] Hydroxychloroquine also protects against preeclampsia.[79] Flares during pregnancy may be difficult to identify because they share characteristics of a normal pregnancy.[77] The complications are more likely in patients with active disease, especially lupus nephritis. If the mother has anti-Ro/SSA or anti-La/SSB antibodies, the fetus is at risk for neonatal lupus with rash, hematologic, hepatic, and cardiac abnormalities including heart block. These risks decrease with continued use of hydroxychloroquine.[77] Treatment of pregnant women with antiphospholipid antibodies is discussed below. Pregnancy should be discouraged in patients with severe pulmonary hypertension, advanced renal insufficiency, severe restrictive lung disease, heart failure, or a history of severe preeclampsia. It is also not advised within 6 months of a severe SLE flare, active lupus nephritis, or a stroke. The best pregnancy outcomes are observed in patients who have had inactive disease for at least 6 months prior to the pregnancy. Drugs used to control the SLE should be those, such as hydroxychloroquine, that can be continued throughout the pregnancy and may decrease the risk of flares, disease activity, and heart block in at-risk pregnancies.[77] Any potentially teratogenic drugs (eg, methotrexate, mycophenolate, cyclophosphamide, and thalidomide) should be stopped before attempting pregnancy.[75] The time before conception is 1 to 3 months for methotrexate and thalidomide, more than 6 weeks for mycophenolate, and 3 months for cyclophosphamide. This also allows time to evaluate whether disease activity is still controlled. Leflunomide should be removed through the oral cholestyramine elimination procedure (8 g three times a day for 11 days with confirmation of undetectable serum concentrations) preferably before conception or at least when pregnancy is confirmed.[75,77] Close monitoring and disease management of the mothers and fetuses are essential during pregnancy. The risks of drug use and harmful effects of disease flare need to be considered.[80] If a flare occurs and an immunosuppressive drug is required during the pregnancy, azathioprine may be considered because limited placental transfer occurs and the fetal liver is unable to metabolize it to its active form.[81,82] The dose should not exceed 2 mg/kg/day. Calcineurin inhibitors (cyclosporine, tacrolimus) are alternative choices. Supplements with calcium, vitamin D, and folic acid should be offered.[80,81] If corticosteroids are needed, maintenance doses should be kept as low as possible (preferably 7.5 mg or less) to decrease the risk of gestational diabetes mellitus, hypertension, infections, pre-eclampsia, and premature rupture of membranes.[66,77] Patients on long-term steroid therapy may need stress doses at the time of delivery. Fluorinated corticosteroids (such as dexamethasone or betamethasone) cross the placenta and should be avoided unless they are being used to treat the fetus.[66] Cyclophosphamide should only be used during the second or third trimester of pregnancy if alternatives failed and the mother's life is in danger.[80,81] If treatment of hypertension is needed, methyldopa, beta-blockers (except atenolol), or calcium channel blockers are considered safe, although there are some concerns about fetal bradycardia and intrauterine growth restriction with beta-blockers.[81] Labetalol is the preferred beta-blocker. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may cause fetal malformations, oligohydramnios, and fetal renal damage.[81] NSAIDs should be discouraged in the preconception period due to concerns of NSAID-induced unruptured follicle syndrome and in the first trimester due to increased risk of miscarriage.[81] They should not be used in the third trimester of gestation because they increase the risk of premature closure of the ductus arteriosus, oligohydramios, neonatal renal failure, and pulmonary hypertension. The safety of selective COX-2 inhibitors during pregnancy is not known. The safety of biologics is also not known, but they can be used preconception. The 2020 ACR guideline strongly recommends continuing certolizumab (which lacks an Fc chain) during pregnancy since minimal placental transfer occurs.[75] The guideline conditionally recommends discontinuation of other TNF-α inhibitors (infliximab, etanercept, adalimumab, golimumab) in the third trimester when placental transfer increases.

The guideline also conditionally recommends stopping anakinra, belimumab, abatacept, tocilizumab, secukinumab, and ustekinumab once pregnancy is confirmed. Rituximab given during the second half of pregnancy can cause neonatal B-cell depletion and should be avoided unless the woman has severe life- or organ-threatening disease.[75] There is insufficient data on the safety of tofacitinib, baricitinib, and apremilast for any recommendation, but they likely cross the placenta.[75] The ACR guideline also included recommendations regarding men planning to father a child. Since cyclophosphamide can damage sperm, it is strongly recommended that men stop cyclophosphamide 12 weeks prior to attempted conception and consider sperm cryopreservation before starting treatment. It conditionally recommends discontinuation of thalidomide 4 weeks before.

SLE–Antiphospholipid Syndrome Overlap

⑧ The antiphospholipid antibodies are a group of antibodies including anticardiolipin, anti-β-2-glycoprotein I, and lupus anticoagulant. They can promote clotting and pregnancy morbidity.[83] Complement also plays a key role in antiphospholipid syndrome (APS) pathogenesis.[84] The diagnosis of APS requires at least one clinical and one laboratory feature. The clinical aspects are vascular events such as venous or arterial thrombi and/or obstetric complications. The obstetric complications meeting the criteria are three or more unexplained consecutive miscarriages before the 10th week of gestation, one or more unexplained deaths of fetuses at or beyond the 10th week of gestation, and one or more births of infants before the 34th week of gestation associated with eclampsia or severe preeclampsia or features of placental insufficiency.[85] Adverse pregnancy outcomes are especially associated with the presence of lupus anticoagulant.[66] Laboratory criteria are the presence of antiphospholipid antibodies on two separate occasions, 12 weeks apart.[85] Antiphospholipid antibodies are found in about 40% of patients with SLE, but less than 40% of those experience thrombotic events.[84] Patients at high risk for thrombotic and obstetric events are those with lupus anticoagulant or a combination of two or three antiphospholipid antibodies or the presence of persistently high antiphospholipid antibody titers.[19] Patients with isolated positive anticardiolipin or anti-β_2-glycoprotein I at low-medium titers, especially if transiently positive, are considered to be at low risk. Patients with thrombosis often have other cardiovascular risk factors (such as hypertension, hyperlipidemia, smoking, or use of estrogen-containing medications) or an underlying autoimmune disease such as SLE.[84] It is recommended that any modifiable factors be controlled. In deciding choice, intensity, and duration of treatment, the clinician should balance benefits with the patient’s risk of bleeding. Consideration should also be given to whether thrombotic events are associated with identified transient precipitating factors. A EULAR Task Force developed recommendations for the management of APS in adults that consider individual risk assessments (Table 107-4).[19]

TABLE 107-4

Recommendations for Thromboprophylaxis in Patients with Systemic Lupus Erythematosus and Antiphospholipid Antibodies

Recommendation	Level of Evidence/Grade of Recommendation
Asymptomatic aPl carriers with no history of thrombosis or pregnancy complications, low-dose aspirin is recommended	2a/B
Patients with no history of thrombosis or pregnancy complications with high-risk aPl profile, low-dose aspirin is recommended	2a/B
Patients with no history of thrombosis or pregnancy complications with low-risk aPl profile, low-dose aspirin can be considered	2b/C
Nonpregnant women with a history of obstetric complications, low-dose aspirin is recommended	2b/B
Patients with APS and first venous thrombosis, warfarin with INR 2-3 is recommended	1b/B
If unprovoked first thrombosis, long-term treatment recommended	2b/B
If provoked first thrombosis, treat as usual.	5D
If provoked first thrombosis with high aPl profile, consider longer treatment	5/D
Patients with APS and recurrent venous thrombosis on warfarin with INR 2-3, consider adding low-dose aspirin or increasing INR target to 3-4 or change to low-molecular-weight heparin	4-5/D
Patients with APS and first arterial thrombosis, warfarin recommended over low-dose aspirin	2b/C
Patients with APS and first arterial thrombosis, warfarin with INR 2-3 or 3-4 recommended	1b/B
Patients with APS and first arterial thrombosis, warfarin with INR 2-3 and low-dose aspirin can be considered	4/C
Patients with APS and recurrent arterial thrombosis on warfarin with INR 2-3, consider adding low-dose aspirin or increasing INR target to 3-4 or change to low-molecular-weight heparin	4-5/D

aPl, antiphospholipid antibodies; APS, antiphospholipid syndrome

Levels of Evidence: 1a: systematic review of randomized controlled trials (RCTs); 1b: individual RCT; 2a: systematic review of cohort studies; 2b: individual cohort study (and low-quality RCT); 3a: systematic review of case-control studies; 3b: individual case-control study; 4: case series and poor-quality cohort and case–control studies; 5: expert opinion

Grade of Recommendation: A: consistent level 1 studies; B: consistent level 2 or 3 studies, or extrapolations from level 1 studies; C: level 4 studies or extrapolations from level 2 or 3 studies; D: level 5 evidence or troublingly inconsistent or inconclusive studies of any level.

Data from Reference 19.

Patients with antiphospholipid antibodies may also have a false-positive test for syphilis (rapid plasma reagin).[18] Other common manifestations of APS are cognitive impairment, thrombocytopenia, stroke or transient ischemic attack, chorea, migraine, glomerulonephritis, avascular necrosis of bones, heart valve lesions, and livedo reticularis.[82]

It is not clear how to treat pregnant women with antiphospholipid antibodies. Low-dose aspirin (75-100 mg) should be considered during pregnancy for those with a high antiphospholipid profile but no history of thrombosis or pregnancy complications (Level 5/D).[19] Those with no history of thrombosis but who have experienced at least three spontaneous miscarriages before 10 weeks gestation and those with fetal loss at 10 weeks or later should be treated with low-dose aspirin and prophylactic doses of heparin (Level 2b/B). Self-administration of low-molecular-weight heparin may be more convenient for patients. Not only does heparin have anticoagulant effects, but it also has anti-inflammatory and immunomodulating properties and can inhibit complement activation.[86] Hydroxychloroquine should also be considered. Those with a history of delivery before 34 weeks gestation associated with eclampsia or severe preeclampsia or placental insufficiency should receive low dose aspirin alone or with prophylactic doses of heparin (Level 2b/B).[19] If women have recurrent obstetric complications despite receiving aspirin and heparin, clinicians should increase the heparin dose to therapeutic (level 5/D) or consider adding hydroxychloroquine (Level 4/D) or low-dose prednisolone (Level 4/D) in the first trimester. Pregnant patients with APS and a history of thrombosis should receive low-dose aspirin with therapeutic doses of heparin (Level 4/C).[19] Warfarin is teratogenic and should be avoided during pregnancy, especially during the first trimester.[77] If low-molecular-weight heparin is used, it should be switched to unfractionated heparin 4 weeks before the anticipated delivery date. The heparin should be discontinued at the start of labor or 8 hours before a planned cesarean delivery.[87] All women with APS should receive anticoagulation with prophylactic doses of heparin, low-molecular-weight heparin, or warfarin for 6 weeks postpartum. Women without thrombosis risks may benefit from just 7 to 10 days of low-molecular-weight heparin.[83] Both heparin and warfarin are safe during breastfeeding.[84]

Clinicians can achieve better control of APS by adding hydroxychloroquine, statins, and vitamin D to standard therapy.[84] For patients who do not respond to conventional APS treatment or for whom it is contraindicated, alternative therapies include other platelet inhibitors, corticosteroids, rituximab, and the complement inhibitor, eculizumab. The role of direct acting oral anticoagulants is not clear. They should not be used for patients who are triple antibody positive or those with arterial thrombi.[19] They may be considered for patients with a low risk profile and no history of arterial thrombosis with a difficult to control international normalized ratio on warfarin.[35]

The most severe form of APS is called catastrophic and is associated with widespread thrombosis, multiorgan failure, and high mortality.[83] Any precipitating factors should be investigated and managed.[19] Treatment consists of combination therapy with glucocorticoids, heparin, and plasma exchange or intravenous immunoglobulins. If ineffective, rituximab or eculizumab may be considered.

Drug-Induced Lupus

⑨ Up to 15% of cases of SLE and up to 30% of cases of subacute cutaneous lupus erythematosus can be attributed to drugs.[88] About 15,000 to 30,000 new cases are reported each year in the United States.[11] These are idiosyncratic reactions precipitated by the interplay of genetic predisposition, concurrent illnesses, environmental factors, and other drugs or foods. Various pathophysiologic mechanisms have been proposed for different drugs in inducing lupus. Most drugs are small molecules that can induce an immune response by binding to larger molecules such as proteins, a process called haptenization. Another proposed mechanism is interference with macrophage uptake of apoptotic or necrotic cells, leading to accumulation of self-antigens. A more recently described mechanism is stimulation of neutrophil extracellular traps (NETs; NETosis), a form of neutrophil cell death that also results in self-antigens that stimulate autoreactive T- or B-cells.[89] Other possible mechanisms are dysregulation and hypomethylation of T-cells.[16]

There are no standard diagnostic criteria because the manifestations of drug-induced lupus are so diverse. The diagnosis is based on lupus-like findings in a patient with no history of the disease and the temporal relationship with the drug, including onset at least 1 month after initiation and improvement in symptoms within days to months after the drug is discontinued. The time frame, however, can be variable. The patient will often have laboratory findings such as a positive ANA or anti-histone antibodies, but usually not anti-dsDNA or anti-Sm antibodies.[90]

Many drugs of varied classes have been implicated. The drugs with the highest risk for inducing traditional symptomatic drug-induced lupus are procainamide (20%) and hydralazine (5%-8%), especially with hydralazine doses over 200 mg/day or a cumulative dose of more than 100 g.[90] It is more common in patients who are slow acetylators.[89] The incidence of positive ANAs with these drugs is 80% to 90% and 50%, respectively.[90] Common manifestations include arthralgias, arthritis, and myalgias. Constitutional symptoms such as fever, fatigue, anorexia, and weight loss are common.[11] Other clinical features include rash, pleuritis, pericarditis, and autoimmune hepatitis. Glomerulonephritis, CNS disease, and hematologic abnormalities are rare in drug-induced lupus.[11] The risk and types of reactions vary depending on the offending drug. Laboratory abnormalities associated with drug-induced lupus include positive ANA and antibodies to histones. Other antibodies such as anti-Sm, anti-dsDNA, and antineutrophil cytoplasmic antibodies (ANCA) may be seen with some drugs. A drug with moderate risk for lupus is quinidine. The incidence of quinidine- and procainamide-induced lupus is declining because of decreasing use of the drugs and use of lower doses. Over 100 drugs of many different classes have been implicated and are considered to be of low risk. Other drugs with well-established links to lupus are minocycline, isoniazid, methyldopa, carbamazepine, and chlorpromazine.[11] A variant of the syndrome is drug-induced subacute cutaneous lupus, which has been most associated with terbinafine and TNF-α inhibitors, but also with calcium channel antagonists, thiazide diuretics, angiotensin-converting enzyme inhibitors, chemotherapeutic agents, phenytoin, carbamazepine, and proton pump inhibitors.[16] The mean age for this syndrome is 59 years; more patients are women, and positive ANA, anti-Ro/SSA, and anti-La/SSB are common, but fewer have anti-histone antibodies than those with drug-induced SLE.[16,89] It may occur after weeks to years of therapy.[89] Chronic cutaneous lupus has been reported with fluorouracil, TNF-α inhibitors, antifungals, and rarely intravenous immunoglobulins.[16] Drug-induced lupus can take weeks to months for skin lesions to resolve after the offending drug has been stopped.[11]

A separate category of drug-induced lupus involves TNF-α inhibitors, such as infliximab, etanercept, adalimumab, golimumab, and certolizumab pegol, and is called TNF-α Antagonist Induced Lupus-like Syndrome (TAILS).[11] These drugs, especially chimeric infliximab, are known to induce autoantibodies. Proposed mechanisms for TNF-α inhibitor-induced lupus are that they induce cell apoptosis, increase the risk for bacterial infection, or suppress T-helper 1 immune response and favor T-helper 2 response. It is common for patients receiving these drugs to develop positive ANAs, anti-dsDNA of the IgM subtype, and extractable nuclear antibodies. Antihistone antibodies are less commonly seen than with other drug-induced lupus. As with traditional drug-induced lupus, the risk of clinical lupus is low compared to the numbers that develop autoantibodies.[90] Rashes and hypocomplementemia are more common features with TNF-α inhibitors than traditional drug-induced lupus.[91] Arthralgias, arthritis, fever, and weight loss are also seen. Renal, hematologic, and neurologic disorders are rare.[11] The underlying diseases being treated with these drugs may be a factor in the development of the observed reactions.

The primary treatment for drug-induced lupus is discontinuation of the implicated drug. Some patients require treatment with corticosteroids or other topical or systemic drugs based on the type and severity of the manifestations. If patients do not improve, a diagnosis of idiopathic SLE should be considered.[11]

Immunizations

Patients with SLE are at increased risk for infections because of immune dysfunction caused by their disease and immunosuppressive therapy. It is important to try to protect patients against these infections, but there are areas of concern regarding the safety and efficacy of vaccines in patients with SLE.[92] SLE cases developing or flaring after vaccine administration have been reported, but the actual risk is low when considering how many people receive immunizations.[93] These reactions may be a response to adjuvants added to increase the immunogenicity of vaccines and could be part of the syndrome called "ASIA—Autoimmune/inflammatory Syndrome Induced by Adjuvants."[93] Another concern is that immunosuppressed patients may have an impaired response to vaccines such as influenza and pneumococcal as compared with healthy individuals. Revaccination may be needed in some cases.[92] Whenever possible, to achieve the best response, vaccines should be administered when SLE is stable and prior to initiating immunosuppressive medications. Non-live vaccines are considered safe in immunosuppressed patients. It is recommended that SLE patients receive pneumococcal vaccine because they are particularly susceptible to *Streptococcus pneumoniae* infections. They should also receive annual influenza vaccines. Those considered to be at risk should be immunized against hepatitis A and B.[92] Live-attenuated virus vaccines, such as measles–mumps–rubella, varicella, intranasal influenza, and yellow fever, are generally contraindicated in patients receiving immunosuppressive therapy. They should be avoided with consideration of risks versus benefits in patients taking high doses of immunosuppressive drugs. Doses of corticosteroids equivalent to prednisone 20 mg/day or more given for at least 2 weeks, methotrexate at 0.4 mg/kg/week or more, and azathioprine at 3 mg/kg/day or higher are considered immunosuppressive.[92] Measles–mumps–rubella boosters for patients on low-grade immunosuppression at risk for measles may be an exception. Non-live vaccines should preferably be given 2 weeks before starting immunosuppressive drugs if possible.[94] Live vaccines should be given at least 4 weeks before starting immunosuppressive drugs.[92] The recombinant zoster vaccine can be given during therapy with immunosuppressive drugs but should not be given during pregnancy. The same pregnancy delay should be observed for live vaccines and the human papilloma vaccine. The meningococcal serogroup B vaccine should only be given during pregnancy if benefits outweigh risks.[95] B-cell–depleting therapy such as rituximab suppresses the humoral response to vaccines, so vaccines should be given 6 months after and 4 weeks before the next course of B-cell–depleting therapy.[92] A patient taking a B-cell–depleting therapy who has a high-risk exposure to tetanus should receive passive immunization with tetanus immunoglobulins. Immunosuppressed patients with SLE should receive a third dose of the same mRNA COVID-19 vaccine at least 28 days after the two-dose primary series.[95]

EVALUATION OF THERAPEUTIC OUTCOMES

⑩ Patients must be assessed for the activity and extent of lupus and monitored for adverse drug reactions. Monitoring for specific drugs is listed in Table 107-3. Many instruments have been developed and modified over the years to assess SLE therapy in trials. It is difficult to assess SLE therapy because milder forms of the disease may fluctuate, regardless of treatment.[96] Examples of measures of disease activity include the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and British Isles Lupus Assessment Group (BILAG). The SLEDAI is a measure of global disease activity that scores 24 manifestations as present or not. Modifications include the SELENA (Safety of Estrogens in Lupus Erythematosus National Assessment)-SLEDAI and SLEDAI-2000 (SLEDAI-2K). The SLEDAI-2K modified some of the elements and has been used in recent trials. Another variation is the SLEDAI-2KG that adds a weighted score based on glucocorticoid dose. BILAG measures clinical disease activity in eight organ systems compared to the prior assessment with a score of 0 to 4. The organ domains are given scores of A to E based on severity with A being severe, B moderate, C mild, D no activity, and E no history. An update of this instrument is the BILAG-2004. Individually, these indices were inadequate for showing superiority of new drugs over standard therapy. To overcome this problem, belimumab investigators developed the Systemic Lupus Erythematosus responder index (SRI) assessment criteria. The SRI has three components: (a) reduction in disease activity by SELENA-SLEDAI by at least 4 points; (b) no new BILAG A and no more than one new BILAG B score; and (c) less than 0.3 point increase (worsening) in physician global assessment (PGA). The PGA assesses patients' general health status. The BILAG-based Combined Lupus Assessment (BICLA) was used to demonstrate the efficacy of anifrolumab. It is defined as improvement in moderate-severe BILAG-2004 activity, no worsening in global and organ-specific disease activity, and no treatment failure. Other proposed instruments are the S2K RI-50 that measures partial improvement and the Lupus Low Disease Activity State (LLDA).[96] Another important assessment of therapy is health-related quality of life (HRQoL), which may use a patient-reported outcomes tool such as the generic 36-item Health Survey Short Form (SF-36) or one designed for cutaneous lupus.[28]

The Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI) may be used for a more comprehensive assessment of disease activity and damage in cutaneous lupus erythematosus and response to therapy.[96]

A British Society for Rheumatology working group developed guidelines for managing SLE in adults. Patients should regularly be evaluated for SLE manifestations, adverse drug reactions, and comorbidities. Those with active disease should be assessed at least every 1 to 3 months with blood pressure, urinalysis, renal function, anti-dsDNA antibodies, complement concentrations, C-reactive protein, complete blood count, and liver function tests with further testing as warranted. Clinical and laboratory assessments should be performed every 6 to 12 months in patients with inactive disease and no organ damage, and more frequently if abnormalities are found.[97]

CONCLUSION

Much progress has been made in understanding the disease processes that lead to the development of SLE. This has led to the development of new drugs that target those disease pathways. Drug approval has been achieved by designing new tools for the assessment of drug efficacy. Therapeutic success is difficult to show when the "placebo" group is receiving standard treatment that usually includes drugs not approved for management of SLE. Practitioners can increase treatment success by educating patients on the importance of adherence to recommended life-style changes and medication regimens.

ABBREVIATIONS

ACR	American College of Rheumatology
ALMS	Aspreva Lupus Management Study

ANA	antinuclear antibody
ANCA	antineutrophil cytoplasmic antibodies
Anti-dsDNA	anti-double-stranded DNA
aPl	antiphospholipid antibodies
APRIL	a proliferation-inducing ligand
APS	antiphospholipid syndrome
BAFF	B-cell activating factor of the TNF family
BICLA	BILAG-based Combined Lupus Assessment
BILAG	British Isles Lupus Assessment Group
BLyS	B-lymphocyte stimulator
CLASI	Cutaneous Lupus Erythematosus Disease Area and Severity Index
CNS	central nervous system
DHEA	dehydroepiandrosterone
DNA	deoxyribonucleic acid
eGFR	estimated glomerular filtration rate
EULAR	European League Against Rheumatism, now European Alliance of Associations for Rheumatology
G6PD	glucose-6-phosphate dehydrogenase
HELLP	hemolysis with elevated liver tests and thrombocytopenia
HRQoL	health-related quality of life
IMPDH	inosine 5-monophosphate dehydrogenase
IL	interleukin
IUD	intrauterine device
La/SSB	antigen La/Sjögren syndrome B antigen
Mesna	sodium-2-mercaptoethane sulfonate
MHC	major histocompatibility complex
MPA	mycophenolic acid

NET	neutrophil extracellular trap
NMDA	*N*-methyl-D-aspartate
NSAID	nonsteroidal anti-inflammatory drug
PGA	physician global assessment
Ro/SSA	antigen Ro/Sjögren syndrome A antigen
RCT	randomized controlled trial
SELENA-SLEDAI	Safety of Estrogens in Lupus Erythematosus: National Assessment-Systemic Lupus Erythematosus Disease Activity Index
SF-36	Medical Outcomes Survey Short Form-36
SLE	systemic lupus erythematosus
SLICC	Systemic Lupus International Collaborating Clinics
SPF	sun protection factor
SRI	SLE Responder Index
TAILS	TNF-α inhibitor-induced lupus syndrome
TNF-α	tumor necrosis factor-alpha
TPMT	thiopurine methyltransferase
Treg	T regulatory cell

SELF-ASSESSMENT QUESTIONS

1. Which of the following individuals would be at the *highest* risk for developing idiopathic SLE?
   - A. 20-year-old African American female
   - B. 25-year-old White female
   - C. 30-year-old Hispanic male
   - D. 40-year-old Asian male
2. There is evidence that SLE can be precipitated in a genetically susceptible individual by:
   - A. Epstein–Barr virus
   - B. Pesticides
   - C. Ultraviolet light
   - D. All of the above
3. A patient is being considered for a trial of a new drug for lupus. She has a malar rash, oral ulcers, and joint tenderness. The study requires that participants fulfill the 2019 EULAR/ACR Classification Criteria for Systemic Lupus Erythematosus. What is required as an entry criterion to consider

this individual for the trial?

A. Anticardiolipin antibody

B. Proteinuria of 1 g in 24 hours

C. Antinuclear antibodies at a titer of least 1:80

D. White blood cell count of 5,000/mm^3 (5 × 10^9/L)

4. Patients with SLE should be encouraged to stop smoking. Which of the following has been associated with smoking?

A. Decreased effectiveness of hydroxychloroquine

B. Decreased titers of anti-double-stranded DNA

C. Decreased incidence of hemorrhagic cystitis with cyclophosphamide

D. Decreased cutaneous lupus disease activity

5. Which of the following drugs decreases survival of B-cells by inhibiting B-lymphocyte stimulator?

A. Abatacept

B. Belimumab

C. Rituximab

D. Tocilizumab

6. A 20-year-old African American woman develops Class III lupus nephritis. What is the recommended induction treatment for her disease?

A. High-dose IV cyclophosphamide

B. Low-dose IV cyclophosphamide

C. Mycophenolate mofetil

D. Rituximab

7. A patient with generalized SLE develops severe neurologic manifestations thought to be related to inflammation. Which of the following drugs has the most evidence supporting its use in this situation?

A. Anifrolumab

B. Belimumab

C. Cyclophosphamide

D. Voclosporin

8. A patient has cutaneous lupus on her face and treatment is needed. She is very concerned about her appearance. Which of the following is *most* associated with causing skin atrophy and telangiectasias?

A. Hydroxychloroquine

B. Methotrexate

C. Topical pimecrolimus

D. Topical triamcinolone acetonide

9. A 35-year-old woman who wants to have a baby in the future is found to have SLE. Which of the following drugs has the *greatest* potential to adversely affect fertility?

A. Azathioprine

B. Cyclophosphamide

C. Hydroxychloroquine

D. Mycophenolate mofetil

10. Which of the following drugs used to treat SLE could be started before pregnancy and continued throughout pregnancy with the *least* potential for harm to a fetus?

A. Cyclophosphamide

B. Dexamethasone

C. Hydroxychloroquine

D. Mycophenolate mofetil

11. A patient with definite antiphospholipid syndrome had her first venous thrombosis and was treated for the acute episode. What should initially be used for secondary thromboprophylaxis for this patient?

A. Low-molecular-weight heparin in prophylactic doses

B. Low-dose aspirin

C. Simvastatin

D. Warfarin adjusted to an international normalized ratio (INR) of 2 to 3

12. What manifestation of SLE is common in idiopathic lupus but rare in drug-induced lupus?

A. Arthritis

B. Nephritis

C. Pleuritis

D. Rash

13. A patient is receiving belimumab for treatment of SLE. His immunization history and needs are being assessed. Which of the following vaccines should be *avoided* while he is receiving that drug?

A. Hepatitis B

B. Influenza

C. Yellow fever

D. Pneumococcal

14. A patient who is going to be treated with cyclophosphamide is considered to be at significant risk for hemorrhagic cystitis. Which of the following will *decrease* her chances of developing this complication?
    A. Alkalinization of urine
    B. Cholestyramine
    C. Folic acid
    D. Mesna
15. Eye examinations are recommended for patients receiving:
    A. Belimumab
    B. Cyclophosphamide
    C. Hydroxychloroquine
    D. Mycophenolate mofetil

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** SLE occurs most frequently in women of reproductive age, especially in nonWhite females. It is most common in those of African origin. See the "Epidemiology" section for more information.
2. **D.** Many environmental factors such as viruses, chemicals, and light can trigger SLE. See the "Etiology" section for more information.
3. **C.** Classification criteria are used to qualify subjects for trials. The EULAR/ACR criteria require that subjects have an ANA titer of at least 1:80 to even consider the other classification criteria. See the "Clinical Presentation" section and Table 107-1 for more information.
4. **A.** Smoking decreases the effectiveness of certain drugs (such as hydroxychloroquine and belimumab), increases cutaneous lupus disease activity, and increases the risk of some adverse drug reactions. Smokers are more likely to have elevated titers of anti-double-stranded DNA. See the "Etiology" and "Nonpharmacologic Therapy" sections for more information.
5. **B.** Belimumab inhibits B-lymphocyte stimulator. Rituximab also affects B-cells but through a different mechanism. See the "Biologic Agents" section under "Pharmacologic Therapy" for more information.
6. **C.** The usual induction treatment for Class III lupus nephritis is cyclophosphamide or mycophenolate mofetil. Low-dose IV cyclophosphamide was shown to be effective in White patients with Western or Southern European backgrounds. African American patients respond less well to cyclophosphamide and may respond better to mycophenolate mofetil. Cyclophosphamide can affect fertility, especially in high doses. Rituximab was not shown to be effective in controlled studies of lupus nephritis but can be tried if other treatments fail. Mycophenolate mofetil would be the best choice for initial induction therapy for this patient. See the "Pharmacologic Therapy" section and Fig. 107-3 for more information.
7. **C.** The EULAR recommendations for the management of neuropsychiatric lupus include cyclophosphamide for treatment of various manifestations. Patients with severe active CNS lupus were excluded from the primary anifrolumab and belimumab studies, although those drugs show promise in some studies. See the "Pharmacologic Therapy" and "Biologic Agents" section for more information.
8. **D.** Topical corticosteroids can cause skin atrophy and telangiectasias. To avoid that, the lowest effective potency and duration should be used. Triamcinolone acetonide is considered to be mid-potency. The low-potency fluocinolone acetonide or hydrocortisone creams would be preferred if a corticosteroid is to be used for the face. See the "Pharmacologic Therapy" section for more information.
9. **B.** Cyclophosphamide is associated with ovarian failure and infertility. This is especially of concern in older women who wish to conceive. See the "Pregnancy and Contraception" section under "Special Populations" for more information.

10. **C.** Hydroxychloroquine is considered safe during pregnancy and can help prevent SLE flares. Cyclophosphamide and mycophenolate mofetil are considered teratogenic. Dexamethasone is a fluorinated corticosteroid. It crosses the placenta and should only be used for treatment of the fetus. See the "Pregnancy and Contraception" section under "Special Populations" for more information.

11. **D.** This patient requires full anticoagulation. See Table 107-4 for more information.

12. **B.** Features of traditional drug-induced lupus include arthritis, pleuritis, and rash. Nephritis is rare. See the "Drug-Induced Lupus" section under "Special Populations" for more information.

13. **C.** Live vaccines should be avoided in patients taking biologic agents. Yellow fever is a live-attenuated virus vaccine. The other choices are inactivated vaccines. See the "Immunizations" section under "Special Populations" section for more information.

14. **D.** Although mesna is only approved for prevention of ifosfamide-induced hemorrhagic cystitis, it is also used with cyclophosphamide. See the "Immunosuppressive Drugs" section under "Pharmacologic Therapy" and Table 107-3 for more information.

15. **C.** Hydroxychloroquine can cause retinal toxicity. This can be minimized with appropriate monitoring. See the "Antimalarials" section under "Pharmacologic Therapy" and Table 107-3 for more information.

Chapter 109: Solid-Organ Transplantation

Nicholas W. Lange; David M. Salerno; Douglas L. Jennings

KEY CONCEPTS

KEY CONCEPTS

① Generally, patients receive a combination of two to four immunosuppressive drugs in order to minimize individual drug toxicities as well as block different pathways of the immune response.

② Antibody preparations that target specific receptors on T cells are classified based on their ability to deplete lymphocyte counts. Most lymphocyte-depleting antibodies are associated with infusion-related reactions, whereas non-depleting agents are generally well tolerated.

③ While the calcineurin inhibitors (CNI) tacrolimus and cyclosporine, inhibitors of interleukin (IL)-2, and thus T-cell activation are the backbone of most immunosuppressive regimens, they are associated with serious adverse effects.

④ Calcineurin inhibitor-induced nephrotoxicity is one of the most common adverse effects observed in solid-organ transplant recipients. Therapeutic drug monitoring is used to optimize the use of calcineurin inhibitors and limit toxicity.

⑤ Corticosteroids are often a component of immunosuppressive protocols. Their adverse effects have led to steroid-minimizing and steroid-free immunosuppressive regimens. Corticosteroids, however, remain a first-line treatment for allograft rejection.

⑥ Azathioprine and mycophenolic acid derivatives inhibit T-cell proliferation by altering purine synthesis. Bone marrow suppression is the most significant adverse effect associated with these agents.

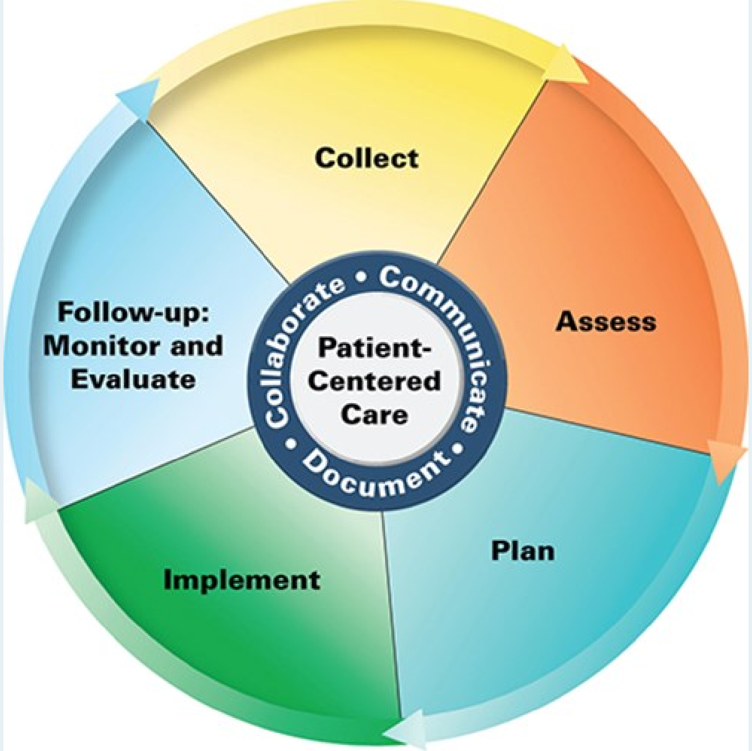
⑦ Sirolimus and everolimus inhibit the mTOR (mammalian target of rapamycin) receptor, which alters T-cell responses to IL-2. The adverse effects associated with these agents include leukopenia, thrombocytopenia, anemia, hyperlipidemia, and impaired wound healing.

⑧ Immunosuppressive agents are frequently involved in drug-drug and drug-food interactions, thus careful assessments of entire drug regimens are paramount.

⑨ Long-term allograft and patient survival are limited by chronic rejection, cardiovascular disease, infection, and malignancy.

PATIENT CARE PROCESS

Patient Care Process for Solid-Organ Transplant Recipient*



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use/marijuana), dietary habits
- Current medications including OTC agents, herbal products, dietary supplements
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), temperature (T), height, weight, O_2-saturation
    - Labs including the measure of end-organ function, hemoglobin (Hgb), platelets, serum creatinine (SCr), immunosuppressant concentrations, white blood cell (WBC) count

Assess

- Presence of over immunosuppression: infectious, adverse drug events
- Presence of under immunosuppression: evidence of end-organ compromise/rejection
- Assess risks based on patient-specific risk factors and time post-transplant

Plan**

- Drug therapy regimen including specific immunosuppressive agents, dose, route, frequency, and duration (Fig. 109-3)
- Monitoring parameters including efficacy (eg, signs and symptoms of rejection) and safety (eg, CBC, SCr, constitutional symptoms); frequency and timing of follow-up

- Patient education (eg, purpose of treatment, dietary and lifestyle restriction, drug-specific information, medication administration)
- Signs and symptoms of rejection (urine output, BP, pain, fever) or infection (temperature) (see Table 109-3)
- Self-monitoring for signs/symptoms of adverse effects (see Table 109-6)
- Referrals to other providers when appropriate

Implement

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, CNI concentration, SCr)

Follow-up: Monitor and Evaluate

- Maintenance of graft functions
- Presence of adverse effects (eg, nephrotoxicity, tremor, hyperglycemia, hypertension, nausea, vomiting) (see Tables 109-6 and 109-7)
- Immunosuppressant TDM results (TAC, CSA, SIR, EVR); adjust IS dose as needed
- Patient adherence to treatment plan using multiple sources of information
- Re-evaluate IS/anti-infective goal of therapy every 3 months

* **New solid-organ transplant recipient in the immediate post-op period.**

** ***Collaborate with patient, caregivers, and other healthcare professionals.***

BEYOND THE BOOK

BEYOND THE BOOK

Visit the International Society for Heart and Lung Transplantation website <https://ishlt.org>. This website contains many useful links, including links to many registries that track outcomes in patients who have undergone heart or lung transplantation. Access the International Thoracic Organ Transplant (TTX) Registry Data slides <https://ishltregistries.org/registries/slides.asp>, and review the Adult Heart Transplantation Statistics. Focus on the slides that pertain to immunosuppression regimens and outcomes. This will aid in the ASSESS and PLAN steps in the patient care process.

INTRODUCTION

Solid-organ transplantation provides a potentially life-saving treatment for patients with end-stage kidney, liver, lung, heart, and intestinal diseases. Over 300 US hospitals offer transplant services, and pharmacists are an integral part of the transplant team.[1] In 2016, almost 600 pharmacists were members of the American College of Clinical Pharmacy's Transplant Practice and Research Network, and more than 65% of responding centers have a pharmacist on their transplant teams.[2] The Centers for Medicare and Medicaid Services regulations require that transplant programs have a multidisciplinary team including representatives from medicine, nursing, nutrition, social services, transplant coordination, and a clinician with experience in pharmacology. While the regulations do not specifically state that each center must include a pharmacist, a pharmacist provides the necessary expertise in transplant pharmacotherapy.

Since 1980, over 630,000 transplants have been performed in the United States, with over half being kidney transplants. A recent analysis estimated that since 1987 over 2.27 million life-years have been saved by transplantation, with an average of 4.3 years per patient.[3] Demand for transplantation continues to grow; since 2010, there has been growth in transplant volume across most all organ types (kidney = 37%, liver = 41%, heart = 52%, lung = 52%).[1] This has been made possible through iterative improvements in the way in which sparsely available organs are allocated to patients with end-stage organ disease. Living donors now account for one-third of all kidney transplants, more than any other organ. Living-donor liver transplantation is also becoming increasingly more common. Efforts to expand the cadaveric donor pool have included relaxation of age restrictions, development of better preservation solutions, deployment of machine perfusion pumps, use of "extended-criteria" and non-heart-beating donors, and the transplantation of split liver allografts into different liver transplant recipients. An increase in deaths related to drug overdose has also resulted in an increased number of organs, often times from donors infected with hepatitis C virus (HCV). With the availability of curative treatments for HCV infection, some transplant recipients may be willing to accept a transplant from and HCV-infected donor. Although controversial, creation of a regulated system for compensating individuals financially for the "donation" of a kidney has been suggested.[4]

Despite these efforts, thousands of people on transplantation waiting lists die each year. Current initiatives to improve organ allocation have included allocation primarily on "medical necessity" versus time on the waiting list. Dialysis can be used for an extended period of time to partially replace the function of the kidneys, and more than half of recent heart transplant recipients receive left ventricular assist devices as a bridge to transplantation. Such life-extending therapies are not readily available for liver and lung transplant candidates, however.

Patient and graft survival rates following transplantation have improved dramatically over the past 30 years as a result of advances in pharmacotherapy, surgical techniques, organ preservation, and the postoperative management of patients (Table 109-1). In this chapter, the epidemiology of end-stage kidney, liver, lung, and heart diseases is briefly reviewed, the pathophysiology of organ rejection is presented, the pharmacotherapeutic options for individualized immunosuppressive regimens are explored in great detail, and the unique complications of these regimens along with the therapeutic challenges they present are discussed.

TABLE 109-1

Organ-Specific Patient and Graft Survival Rates

	Patient Survival (%)		Graft Survival (%)	
Organ	**1 year**	**5 years**	**1 year**	**5 years**
Kidney				
Living donor	97.9	89.4	97.5	85.6
Deceased donor	94.3	80.4	93.2	74.5
Liver				
Living donor	96.2	77.6	93	77.3
Deceased donor	93.8	71.9	92.1	71.9
Heart				
Cardiomyopathy			91.6	79.4
Coronary artery disease			89.1	71.9
Lung				
Single	85.8	35.8	85.4	45.5
Double	83.3	47.3	87.3	55.7

KIDNEY

Etiology of End-Stage Kidney Disease

End-stage kidney disease is defined as a glomerular filtration rate (GFR) of < 15 mL/min/1.73 m^2 (0.14 mL/s/m^2) or receipt of renal replacement therapy.[5] The most common causes of end-stage renal disease (ESKD) leading to transplantation are diabetes, hypertension, glomerulonephritis, and polycystic kidney disease.[6]

Epidemiology

The number of prevalent ESKD patients in 2018 was 785,883, which increased by 3.2% relative to 2017.[7] The adjusted prevalence of ESKD increased to 2,242 cases per 1 million people in 2018 (a new high). The vast majority of patients with ESKD undergo intermittent hemodialysis treatment at a medical facility, though a growing percent of patients undergo home hemodialysis or peritoneal dialysis. The number of patients on the kidney transplant waiting list as of December 31, 2019, was 101,337 which was relatively unchanged compared to those on the waiting list as of December 31, 2014.[6] In 2019, a total of 24,273 kidney transplants were performed. This was an approximate 10% increase relative to the total number of kidney transplants performed in 2018.[6] This was largely driven by deceased donor transplants secondary to increasing acceptance of organs procured from HCV-positive donors. Patients who do not have compatible living donors are placed onto a national waiting list for a deceased donor kidney. Deceased donor kidneys are allocated by the Kidney Allocation System, which considers patient-specific factors such as time on the wait list or time undergoing dialysis, high degree of immune-sensitization, and patient age.[8,9]

At 1-year and 5-year post-transplantation, graft survival was 95.7% and 83.2%, respectively, among patients who underwent deceased donor transplantation between 2012 and 2014. Alternatively, recipients who underwent surgery in the same time period but received a kidney transplant from a living donor experienced 1-year and 5-year graft survival rates of 96.9% and 91.4%, respectively.[6] Median patient survival after kidney transplantation is 12 years.[10]

Physiologic Consequences of Transplantation

The glomerular filtration rate of a successfully transplanted kidney may be near normal almost immediately after transplantation. In some patients, however, the concentration of standard biochemical indicators of kidney function, such as serum creatinine and blood urea nitrogen, may remain elevated for several days or even weeks to months. Standard formulas used to predict drug dosing rely on a stable serum creatinine and thus may be inaccurate or misleading immediately following transplantation. Although the allograft is able to remove uremic toxins from the body, it may take several weeks for other physiologic complications of ESKD—such as anemia, calcium and phosphate imbalance, and altered lipid profiles—to resolve. The renal production of erythropoietin and 1-hydroxylation of vitamin D may return toward normal early in the postoperative period. Because the onset of physiologic effects may be delayed, continuation of the patient's pre-transplantation vitamin D, calcium supplementation, and/or phosphate binders may sometimes be warranted. Patients should be monitored for hypophosphatemia and hypercalcemia for the first few days to weeks after kidney transplantation.

Delayed graft function (DGF) is characterized by the need for dialysis in the first post-operative week.[11] The incidence of DGF in deceased donor kidney transplantation ranges from 10% to 50% and results in a slower return of the kidney's excretory, metabolic, and synthetic functions. DGF is associated with a prolonged hospital stay, higher costs, difficulty managing immunosuppression, slower patient rehabilitation, and lower graft survival.[12] Other early causes of impaired kidney function such as ureteral obstruction, renal artery stenosis, or other technical vascular complications, thrombosis, or rejection should be distinguished from DGF.

General Immunosuppressive Strategy Considerations

Induction

Potent immunosuppressive agents administered parenterally around the time of transplant surgery are referred to as induction therapies. The goal of administering induction immunosuppression is to prevent early cellular- or antibody-mediated.[13] Induction therapies are antibody preparations given most typically along with high doses of corticosteroids. They can be categorized as depleting or non-depleting.[14] Depleting agents include anti-thymocyte globulin preparations (Thymoglobulin, Atgam) and alemtuzumab, whereas the only non-depleting agent is basiliximab. In 2019, 91% of kidney transplant recipients received induction immunosuppression at the time of transplantation.[6] Among kidney transplant recipients at a higher risk for rejection (eg, those undergoing repeat transplantation or those with pre-formed antibodies against their donor) depleting agents should be preferentially administered due to their superiority at preventing acute rejection.[15–17]

Maintenance

Maintenance immunosuppressive therapies are administered to transplant recipients for the duration of the functional life of their transplanted organ, also with the goal of preventing acute rejection. Maintenance immunosuppression regimens are most commonly composed of different agents targeting different pathways or immune system effector cells to ensure adequate immunosuppression as well as increase drug tolerability. The most commonly deployed agents in maintenance immunosuppressive cocktails include the calcineurin inhibitors, anti-metabolites, mammalian target of rapamycin (mTOR) inhibitors, co-stimulation antagonists, and corticosteroids.[18] Between the two available calcineurin inhibitors, tacrolimus is more potent and is generally preferred over cyclosporine due to a decrease in the incidence of acute rejection.[19,20] Similarly, mycophenolate is generally the preferred anti-metabolite relative to azathioprine.[21] These drugs will all be reviewed in detail later in this chapter.

In 2019, the vast majority of kidney transplant recipients were initiated on regimens consisting of tacrolimus (a calcineurin inhibitor; CNI), mycophenolate (an anti-metabolite), +/− a corticosteroid.[6] Belatacept, a co-stimulation antagonist that first gained FDA approval for use in kidney transplantation in 2011, has been incorporated into CNI-sparing or CNI-avoiding immunosuppressive regimens in kidney transplant recipients owing to its more tolerable side effect profile and potential to improve long-term patient and graft outcomes.[22,23]

LIVER

Etiology of End-Stage Liver Disease

Noncholestatic cirrhosis (hepatitis C, alcoholic cirrhosis, hepatitis B, nonalcoholic steatohepatitis, and autoimmune hepatitis) is the primary cause of end-stage liver disease, and more than 70% of liver transplant recipients have been diagnosed with one of these conditions.[24] Other indications for transplantation include acute liver failure, autoimmune hepatitis, primary biliary cholangitis, and primary sclerosing cholangitis. Nonalcoholic steatohepatitis represents a growing indication for liver transplantation, while hepatitis C-related indications are declining.

In general, active substance abuse has been a contraindication to liver transplantation, but given the high mortality for acute alcoholic hepatitis and the current lack of viable treatments, this is an area of growing research worldwide. A number of US centers have expanded transplantation in this patient population.[25] Additionally, active or recent malignancy is a contraindication to any transplantation, with the exception of hepatocellular carcinoma meeting specified criteria for liver transplantation.[26,27]

Epidemiology

According to the CDC National Center for Health Statistics 2018 report, there are 4.5 million adults diagnosed with liver disease in the United States, which resulted in nearly 45,000 deaths attributable to liver disease.[28] In 2019, the total prevalence of patients on the United States liver transplant waitlist was over 25,000. However, only 8,896 patients underwent liver transplantation.[24]

Liver allografts are allocated based on a United Network for Organ Sharing-adapted Model for End-stage Liver Disease (MELD) score.[29,30] This score—which is calculated from the patient’s serum creatinine concentration, total serum bilirubin concentration, international normalized ratio, and serum sodium concentration—accurately predicts short-term mortality in patients with cirrhosis. Patients listed for liver transplants are prioritized based on acuity, as measured by MELD score, rather than time on the waitlist.

The median survival after liver transplantation is 11 years and is increasing in recent years. Graft failure occurred in 6.6% of deceased-donor liver transplant recipients at 6 months and 8.9% at 1 year for transplants performed in 2018. Five-year and 10-year patient survival is now 80% and 60%, respectively.[24]

Physiologic Consequences of Transplantation

The physiologic consequences of liver transplantation are complex, involving changes in both its metabolic and synthetic function. Postoperatively, the liver transplant recipient will likely have many fluid, electrolyte, and nutritional abnormalities. Biliary tract dysfunction may alter the absorption of fats and fat-soluble drugs.[31] Poor absorption of the lipid-soluble drug cyclosporine improves after successful liver transplantation and reestablishment of bile flow. Vitamin E deficiency and its neurologic complications are usually reversed after successful liver transplantation. In stable adult liver transplant patients, the concentrations of retinol and tocopherol are similar to those seen in normal healthy subjects, indicating recovery of liver production and excretion of bile salts needed for fat-soluble vitamin absorption. Table 109-2 summarizes the effects of liver transplantation on metabolism and renal elimination that are seen in the immediate postoperative period. Most of these changes resolve as liver function normalizes.

TABLE 109-2

Perioperative Changes in Drug Disposition and Elimination Following Liver Transplantation

	Result	Comment
Serum proteins		
↓ Albumin	↑ Free fraction of drugs usually bound to albumin	Diazepam, salicylic acid binding greater in liver transplant than in chronic liver disease because of endogenous binding inhibitors (up to 45 days post-transplant)
↑ Alpha-1-acid glycoprotein	Lower unbound fraction of drugs	Lidocaine
Metabolism/elimination		
Microsomal enzymes	↑ CYP2E1 activity	Increased drug metabolism (induction)
	↔ CYP2D6	Unaffected
	↓ CYP activity	Decreased drug elimination (inhibition)
Oxidation	Stable	
Conjugation	Normalizes after transplant	
Biliary function	↓ Absorption of lipophilic compounds	
	↑ Cyclosporine metabolites in blood	
Renal elimination	Elimination of gentamicin, vancomycin, cephalosporins less than predicted by serum creatinine	Renal elimination of metabolites limited

General Immunosuppressive Strategy Considerations

Induction

Antibody therapy is seldom used as induction in liver transplantation. In 2019, nearly 80% of liver transplant centers in the United States did not utilize induction therapy (with the exception of corticosteroids) due to the reduced immunogenicity of liver allografts relative to other solid organs.[24] Instead, both basiliximab and anti-thymocyte globulin have been utilized to allow for a delay in the introduction of CNIs in the setting of residual hepatic encephalopathy or renal dysfunction post-transplant.[32–34]

Maintenance

Maintenance immunosuppressive therapy for liver recipients in most transplant centers includes a CNI with an anti-metabolite agent with or without steroids.[24] More than 60% of transplant centers use three initial agents, though regimens consisting of two or four agents have also been utilized.

mTOR inhibitors are infrequently used in maintenance regimens in liver transplant recipients, and use has been muted by an FDA boxed warning outlining a risk of hepatic artery thrombosis when used within 30 days of transplant.[35] Belatacept is not utilized post-liver transplantation secondary to an increase in mortality following its use.[36]

LUNG

Etiology of End-Stage Lung Disease

End-stage lung disease is generally defined as the inability of the lungs to carry out routine gas exchange.[37] The most common causes of end-stage lung disease leading to transplantation are restrictive lung diseases (eg, idiopathic pulmonary fibrosis, sarcoidosis), cystic fibrosis, chronic obstructive pulmonary disease (COPD), and pulmonary arterial hypertension.[38] The Pulmonary Transplantation Council of the International Society for Heart and Lung Transplantation (ISHLT) released an updated consensus document in 2014 outlining recommendations for selecting lung transplant candidates, which dictates that transplantation should only be offered to patients who (1) are at high risk (>50%) of death within 2 years if transplantation is not performed, (2) have a high likelihood (>80%) of surviving at least 90 days post-operatively, and (3) have a high likelihood (>80%) of surviving at least 5-year post-transplant assuming there is adequate lung allograft function.[39]

Epidemiology

There is no universally accepted definition for the diagnosis of end-stage lung disease and thus quantifying the incidence is challenging. Rather, conditions that lead to lung disease may have their own respective stages to quantify disease severity, such as with COPD. The Global Initiative for Chronic Obstructive Lung Disease defines stage 4 lung disease as an FEV_1 of <30% expected.[40] The number of patients on the lung transplant waiting list as of December 31, 2019, was 1,423 which was reduced compared to those on the waiting list as of December 31, 2014 (n=1,683) due to the increasing rate of increase in lung transplants performed annually.[38] In 2019, a total of 2,759 lung transplants were performed which was an increase of 7.6% relative to 2018.[38] Lung transplants are allocated on the basis of the Lung Allocation Score (LAS), which is calculated using patient-specific factors predictive of survival while on the waitlist as well as factors predictive of survival 1-year post-transplant.[41]

Relative to all other solid-organ transplant recipients, those patients who undergo lung transplantation experience the lowest overall survival at all measured time points.[38] In 2016, data analyzed from the ISHLT registry of all lung transplant recipients who underwent transplant between 1990 and 2014 indicated that median patient survival was 5.8 years.[42] Ten-year survival is approximately 33%.

Physiologic Consequences of Transplantation

In the absence of graft dysfunction, gas exchange and parameters of ventilation (tidal volume, minute ventilation, respiratory rate, etc.) after lung transplantation are generally normal relative to those of an otherwise healthy patient without lung disease. Notable differences in pulmonary physiology and function do exist, however. An impaired cough reflex and impaired mucociliary clearance due to at least partial pulmonary denervation increase the risk of infection.[43] Phrenic nerve injury during complex transplant surgery may lead to diaphragmatic paralysis, which complicates post-transplant rehabilitation and is associated with prolonged hospitalization.[44] Right ventricular dysfunction (see Chapter 46) may be observed in the setting of post-operative pulmonary arterial hypertension.[45] Among recipients of single lung transplants (as compared to double lung transplantation), infections may develop in the allograft from a native lung source.[46] The upper airways are also a potential source of pulmonary infection, especially among patients with cystic fibrosis, who are often colonized with multi-drug resistant bacteria prior to transplantation.[47] Allograft dysfunction, regardless of the underlying causes, manifests most commonly as shortness of breath due to impaired gas exchange.

General immunosuppressive strategy considerations

Induction

In 2019, 78% of lung transplant recipients received induction immunosuppression at the time of transplantation.[38] Evidence guiding the selection of induction agents in lung transplantation is often of lower quality. Single-center, retrospective evaluations generally indicate a lower incidence of acute rejection but a higher incidence of infections among recipients of depleting agents.[48]

Maintenance

In 2019, the vast majority of lung transplant recipients were initiated on regimens consisting of tacrolimus, mycophenolate, and a corticosteroid.[38] Tacrolimus is the only FDA-approved immunosuppressive agent for use in lung transplants, which can complicate lung transplant recipients' access to their necessary, life-sustaining medications.[49]

A serious, immunologically mediated complication post-lung transplantation is the development of bronchiolitis obliterans syndrome (BOS), also referred to as chronic lung allograft dysfunction (CLAD) or chronic rejection. There are no universally effective treatments for the management of BOS, but various therapeutic approaches have promise in preventing its development. These strategies may include the use of mTOR inhibitors in maintenance immunosuppression as well as the addition of azithromycin, montelukast, and even statins into medication regimens.[50–54]

HEART

Etiology of End-Stage Heart Disease

Advanced heart failure (ie, stage D) can be defined in several ways. Typically these patients have advanced symptoms (eg, New York Heart Association class III or IV) despite maximal medical management. Many patients with advanced heart failure will be frequently admitted to hospital, and most cannot tolerate adequate doses of standard heart failure drug therapies such as ACE inhibitors and beta-blockers.[55] Once in the advanced stage of the disease, patients have an expected 1-year mortality risk of 80% or greater without a heart transplant or a left-ventricular assist device implantation.[56] Idiopathic cardiomyopathy and ischemic heart disease account for heart failure in more than 90% of heart transplantation recipients.[57] Other etiologies include uncontrolled hypertension, valvular disease, genetic cardiomyopathy, chronic alcohol abuse, amyloidosis, cardiac sarcoidosis, congenital heart disease, peripartum cardiomyopathy, and retransplantation for graft atherosclerosis or dysfunction. The role of heart transplant as a therapeutic option for patients with heart failure is discussed in Chapter 36.

Epidemiology

From 2008 to 2019, the number of new listings for heart transplant in the United States increased by 42.5%, from 2,867 to 4,086.[57] The number of candidates awaiting heart transplant increased by 42.6% over 2008 to 2019, from 5,304 to 7,562. The median wait time in 2018 to 2019 was 5.1 months, the lowest in the past decade. The number of heart transplants performed in the United States has steadily risen, albeit slowly, and in 2019 was at 3,597. Adult death rates after heart transplant continued to decline; of those who underwent transplant in 2018, 6.4% died by 6 months and 7.9% died by 1 year.[57] The median survival after heart transplant surgery is 12 to 13 years.[58]

Physiologic Consequences of Transplantation

In the native heart, the sympathetic and parasympathetic nervous systems exert powerful control over heart rate and contractile force. During the surgery, the transplanted heart is denervated and no longer responds to physiologic stimuli and pharmacologic agents in a normal manner.[59] In situations requiring an increased heart rate such as exercise or hypotension, the denervated heart is unable to increase heart rate but instead relies on increasing the stroke volume. Later in the course of exercise or hypotension, heart rate increases in response to circulating catecholamines. While the maximum exercise capacity of heart transplant recipients is below normal, most patients are able to resume normal lifestyles and participate in reasonably vigorous activities.[59]

A number of autoregulatory and physiologic responses present in the normal heart are interrupted or blunted for the first 6 weeks after transplantation. The donor sinus node function may be impaired as the result of the preservation regimen, direct surgical trauma at excision, the presence of long-acting antiarrhythmics (eg, amiodarone) taken prior to transplant by the recipient, and a lack of "conditioning" responsiveness to catecholamines.[60] Consequently, the transplanted heart generally requires chronotropic support with either dobutamine, dopamine, or pacing in the perioperative period to maintain a heart rate greater than 110 beats/minute and satisfactory hemodynamics (ie, blood pressure, urine output, and tissue perfusion).[61]

Right ventricular function is frequently impaired, presumably as a result of preservation regimen injury and elevated pulmonary vascular resistance. Common treatments for right-heart failure include intra- or postoperative administration of pulmonary vasodilators (eg, nitric oxide) and inotropic agents like milrinone and dobutamine.[62]

A “restrictive” hemodynamic pattern may be present initially but usually improves in 6 weeks following transplantation. Donor–recipient size mismatch may contribute to early post-transplantation hemodynamic abnormalities characterized by higher right and left ventricular end-diastolic pressures. Tachyarrhythmia (eg, nonsustained ventricular tachycardia) is usually transient and may result from the use of catecholamines or milrinone.

Myocardial depression frequently occurs as a result of non-immune-related graft injury from cold ischemia and generally requires temporary inotropic support with agents such as dobutamine, milrinone, and epinephrine. Severe forms of myocardial depression/injury can manifest as sustained hypotension and low cardiac output—a syndrome known as primary graft dysfunction (PGD)—which can be severe enough to require temporary mechanical circulatory support.[63]

General Immunosuppressive Strategy Considerations

Induction

The available evidence does not suggest a consistent benefit for induction immunosuppression in terms of improving post-transplant survival or reducing rates of acute rejection after heart transplantation. As such, the use of induction therapy is not uniform, and fewer than 50% of heart transplant recipients receive this therapy at the time of surgery.[64] Considerations favoring the use of induction therapy after heart transplantation include high-risk immunologic features (ie, allosensitization) or the need to delay calcineurin inhibitor initiation in the setting of renal injury. Of the available agents, basiliximab is the most commonly used agent for induction, followed by thymoglobulin.[64]

Maintenance

The standard maintenance immunosuppression regimen immediately after heart transplantation is triple therapy with a calcineurin inhibitor (usually tacrolimus), mycophenolate mofetil, and prednisone. While most patients will remain on tacolimus and mycophenolate long-term, prednisone is frequently tapered off by the end of the first post-transplant year.[64] If patients develop chronic rejection or renal injury from calcineurin inhibitors, mTOR inhibitor can be substituted either for tacolimus or mycophenolate as long-term immunosuppression.[65] To date, newer agents like belatacept have not been studied after heart transplantation.

PATHOPHYSIOLOGY OF REJECTION

Rejection of a transplanted organ can take place at any time following surgery. Rejection can be differentiated based on time from transplantation (eg, early vs late) and/or by the pathophysiologic processes that underlie the rejection. Classically, this would include hyperacute rejection, acute, or chronic rejection, with further immunologic classification as either cellular rejection, antibody-mediated rejection, or some combination thereof.

General Concepts

Rejection is primarily mediated by activation of alloreactive lymphocytes (Fig. 109-2). T-cells and antigen-presenting cells (APC) such as B-cells, macrophages, and dendritic cells coordinate to create a toxic, inflammatory milieu targeting non-self tissue (eg, the transplanted organ).[66]

FIGURE 109-2

T-cell activation and sites of action of immunosuppressive agents. The TCR recognizes antigens bound to the MHC. A costimulatory signal is required for T-cell activation: the CD80/CD86-CD28 interaction from the APC to the T cell. Activation leads to IL-2 production (in a positive-feedback loop) and a host of other events, some of which are bracketed in the lower right-hand corner. Numerous agents are available to suppress T-cell activation. Belatacept blocks the CD80/CD86-CD28 interaction. Cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FKBP, respectively), forming a complex that inhibits the phosphatase calcineurin and the calcineurin-catalyzed dephosphorylation that permits translocation of NFAT into the nucleus. NFAT is required for transcription of IL-2 and other growth and differentiation–associated cytokines (lymphokines). Sirolimus (rapamycin) and everolimus work downstream of the IL-2R, binding to FKBP; the FKBP-sirolimus complex binds to and inhibits the mTOR, a kinase involved in cell cycle progression (proliferation). MMF and azathioprine inhibit nucleic acid synthesis, thereby inhibiting T-cell proliferation. The antibody muromonab (OKT3) inhibits TCR function via interaction with its CD3 component. Daclizumab and basiliximab block IL-2 signaling by interacting with the alpha subunit of the IL-2R complex (CD25). Several antibodies can block the systemic effects of released TNF. Alemtuzumab, by binding to CD52, marks the cell for destruction, thereby depleting $CD52^+$ cells. Chromosome 6 contains an extremely polymorphic region of DNA known as the human leukocyte antigen (HLA) system, which encodes the blueprint for the expression of self-antigen on every nucleated cell in the body.[67] The first event that occurs in the complex sequence of organ rejection is the recognition of foreign, non-self molecules. This is facilitated primarily by APC that recognizes either class I (eg, HLA-A, -B, and -C) or class II (HLA-DR, -DP, and -DQ) antigens that are expressed throughout the allograft. Antigen-specific T-cell activation proceeds, leading to graft injury/destruction. The specifics of this immune cascade of organ rejection are discussed in Chapter e106.

Hyperacute Rejection

Hyperacute rejection occurs when pre-formed donor-specific antibodies are present in the recipient at the time of the transplant. These may be anti-HLA antibodies or anti-ABO antibodies between donor and recipient with incompatible blood group types. Due to the "primed" nature of this immune response, it can be evident within minutes of graft reperfusion. Tissue damage is mediated through antibody-dependent, cell-mediated cytotoxicity, or through activation of the complement cascade. The ischemic damage to the microvasculature rapidly results in tissue necrosis and ultimately graft failure.[68]

Hyperacute rejection has become uncommon in solid-organ transplantation with the advent and subsequent advancement of crossmatching. A positive lymphocytotoxic crossmatch presents a serious risk for graft failure even if hyperacute rejection does not occur.[69] A negative crossmatch does not entirely rule out the possibility of hyperacute rejection because non-HLA antigens on the vascular endothelium can serve as targets of donor-specific antibodies.

Acute Cellular Rejection

Acute rejection is the most common form of allograft rejection, typically occurring in the first few months following transplantation, though it can occur at any time during the life of the allograft. With acute cellular rejection, alloreactive T-lymphocytes appear in the circulation and infiltrate the allograft through the vascular endothelium. Cytotoxic T-cells specifically target and damage functioning cells in the allograft. At the same time, local release of lymphokines attracts and stimulates macrophages to cause tissue damage through a delayed hypersensitivity-like mechanism. These immunologic and inflammatory events lead to nonspecific signs and symptoms including pain and tenderness over the graft site, fever, and lethargy. End-organ dysfunction is often evident, especially in patients with higher-grade ACR (Table 109-3). Strategies to reverse acute cellular rejection include the addition of an additional maintenance agent(s), bolus corticosteroids with a taper, and possibly lymphocyte-depleting therapy (Fig. 109-3).

TABLE 109-3

Acute Cellular Rejection After Transplant

	Percent of Patients With ≥1 Rejection Event Within the First Year Post-transplant	Signs/Symptoms of Rejection	Monitoring Strategies for Detecting Rejection
Kidney	7.1%	Elevated SCr, BUN, reduced UOP	Biopsy
Liver	12.3%	Elevated AST/ALT/Alkaline Phosphatase	Biopsy
Lung	16%	Reduced PFT, hypoxia, shortness of breath	PFT, bronchoscopy, biopsy
Heart	25.1%	Reduced ejection fraction, new dysrhythmia, overt heart failure	Right heart catheterization, echocardiogram, electrocardiogram, biopsy

SCr, serum creatinine; BUN, blood urea nitrogen; UOP, urine output; AST, aspartate transaminase; ALT, alanine transaminase; PFT, pulmonary function tests

Antibody-Mediated Rejection

Antibody-mediated rejection (AMR), sometimes referred to as vascular or humoral rejection, is characterized by the presence of donor-specific antibodies directed against HLA antigens present on the allograft vascular endothelium. The antibodies activate complement, which leads to the formation of the membrane attack complex that directly damages the allograft tissue and further attracts inflammatory cells. The resultant damage is histologically distinct from cellular rejection and involves microvascular injury.[70] Definitive diagnosis of AMR is based on the presence of three clinical features: presence of donor-specific antibodies, immunofluorescence staining of complement deposits in the microvasculature, and evidence of allograft dysfunction.[71,72] Circulating immune complexes often precede humoral rejection. This form of rejection is less common than cellular rejection and often occurs in the first 3 months after transplantation.[71] An increased risk of humoral rejection is associated with female sex, elevated PRA, and a positive crossmatch.[72] Strategies to reverse humoral rejection may include plasmapheresis, often in combination with intravenous immunoglobulin, high-dose intravenous corticosteroids, lymphocyte-depleting agents, bortezomib, rituximab, and augmented background maintenance immunosuppression.

Chronic Rejection

Chronic rejection is a major cause of graft loss. It presents as a slow and indolent form of ACR, in which the humoral immune system and antibodies against the vascular endothelium appear to play a role. Persistent perivascular and interstitial inflammation is a common finding. As a result of the complex interaction of multiple drugs and diseases over time, it is difficult to delineate the true nature of chronic rejection. While chronic rejection of the kidney, liver, or lung allograft is generally not amenable to drug therapy, 3-hydroxy-3-methylglutaryl-coenzyme A (HMGCoA) reductase inhibitors are given to all heart transplant recipients to decrease the incidence of chronic rejection and prolong survival (Table 109-4).[73] The mTOR inhibitors sirolimus and everolimus may also decrease the incidence and slow progression of cardiac allograft vasculopathy; however, these agents are hampered by side effects and cannot be used in the early post-transplant setting (Table 109-4).[73]

TABLE 109-4

Strategies for Preventing Cardiac Allograft Vasculopathy (CAV)

Drug Class	Drugs	Dose	Timing of Initiation
Statins	Pravastatin Simvastatin Atorvastatin Rosuvastatin	20-40 mg daily 5-20 mg daily 10-40 mg daily 5-20 mg daily	Prior to hospital discharge
mTOR inhibitors	Everolimus Sirolimus	0.75 mg twice daily 1-2 mg daily	Not recommended to initiate within 6 months of transplant due to impaired wound healing. However, greatest benefit is realized if started within 1-2 years
Glycemic control	Insulin, other anti-hyperglycemic agents	Titrate to euglycenmia	Immediately post-transplant
Prevent ACR[a]	Tacrolimus Cyclosporine	Titrate to center-specific trough values	Immediately post-transplant
Prevent CMV infection[b]	Valganciclovir	900 mg daily (adjusted for kidney function)	Immediately post-transplant

ACR, acute cellular rejection; CMV, cytomegalovirus

[a] Episodes of acute cellular rejection increase the subsequent risk of developing CAV.

[b] CMV infection has been linked to accelerated development of CAV. Prophylaxis with valganciclovir is only recommended in recipients at high risk of infection post-transplant.

IMMUNOSUPPRESSIVE MEDICATIONS FOR THE PREVENTION AND TREATMENT OF REJECTION

Rejection is both prevented and treated with combination drug therapy. A multi-drug approach is rational because immunotherapy agents have potentially synergistic mechanisms of action. Furthermore, the use of a multi-drug immunosuppression regimen may allow the use of lower doses of individual agents, thus reducing the severity of dose-related adverse effects (Fig. 109-3). Immunosuppression protocols tend to be medical center specific, and further tailoring of patient-specific regimens is standard practice.[61,74,75]

Depleting Antibody Therapies

Anti-thymocyte Globulin (ATG)

Two ATG formulations are available in the United States: ATG (Atgam, Pfizer, New York, NY), an equine polyclonal antibody, and RATG (Thymoglobulin, Genzyme, Cambridge, MA), a rabbit polyclonal antibody. The rabbit preparation is less immunogenic and hence has improved tolerability over the equine preparation.

Pharmacology/Mechanism of Action

Because of their polyclonal antibody nature, both ATG and RATG exert their immunosuppressive effect by binding to a wide array of lymphocyte receptors such as CD2, CD3, CD4, CD8, CD25, and CD45. Binding of ATG or RATG to the various receptors results in complement-mediated lysis and subsequent lymphocyte depletion. While T cells are the major lymphocytic target for the compounds, other blood cell components such as B cells and other leukocytes are also affected (see Fig. 109-2).

Pharmacokinetics

ATG is poorly distributed into lymphoid tissue and binds primarily to circulating lymphocytes, granulocytes, and platelets. The terminal half-life of ATG is 5.7 days. RATG has a volume of distribution of 0.12 L/kg, and its terminal half-life in kidney transplant recipients is significantly longer than ATG at 30 days.[76] Peak plasma concentrations are reached after 5 to 7 days of ATG or RATG infusions.

Efficacy

ATG and RATG are used for the treatment of acute allograft rejection or as induction therapy to prevent acute rejection.[77] When compared head-to-head in kidney transplant recipients, RATG resulted in less frequent and less severe acute rejection episodes, fewer serious adverse events and was superior with respect to the composite endpoint including freedom from death, graft loss, or rejection.[78] RATG received regulatory approval as induction therapy in kidney transplantation.[79] As such, RATG is both preferred over ATG for induction and treatment of rejection in solid-organ transplant recipients.

Use of RATG in liver transplantation as part of a steroid avoidance protocol is associated with similar rates of patient and graft survival and acute rejection compared with dual or triple therapy.[34] In kidney transplant, RATG is associated with improved graft survival at 5 years as compared with equine ATG. Quadruple-drug therapy results in similar rates of patient and graft survival in heart transplant recipients, with a lower rate of acute rejection at 1 year compared with triple-drug therapy. Outcomes associated with RATG in lung transplantation have not consistently demonstrated favorable outcomes related to acute rejection or patient and graft survival.[80,81]

Adverse Effects

Most adverse effects reported with ATG and RATG are related to the lack of specificity for lymphocytes. Dose-limiting myelosuppression (leukopenia, anemia, and thrombocytopenia) occurs frequently. Other adverse effects include anaphylaxis, hypotension, hypertension, tachycardia, dyspnea, urticaria, and rash. Serum sickness is seen more frequently with ATG than with RATG. Nephrotoxicity is rare in the absence of serum sickness. Infusion-related febrile reactions are common; therefore, all patients should be pre-medicated with acetaminophen, diphenhydramine, and corticosteroids. Finally, as with any immunosuppressive agent, ATG and RATG are associated with an increased risk of infections—particularly viral infections—and malignancy.

Drug-Drug and Drug-Food Interactions

There are no known drug or food interactions with ATG or RATG.

Dosing and Administration

ATG doses range from 10 to 30 mg/kg/day as a single dose for 7 to 14 days. A skin test (test dose) is required prior to administration of the initial dose of ATG. RATG is a more potent compound and is administered at doses of 1 to 1.5 mg/kg/day as a single daily dose for 7 to 14 days for acute rejection or for 3 to 10 days for induction of immunosuppression. ATG and RATG should both be administered through a central line or through a high-flow vein with an in-line 0.22-micron filter over at least 4 hours to minimize phlebitis and thrombosis.[76] Heparin and hydrocortisone are commonly added to the infusion to minimize phlebitis and thrombosis.[76]

Alemtuzumab

Alemtuzumab is approved for use in B-cell chronic lymphocytic leukemia.[82] However, its effects on depleting both T and B lymphocytes make it useful in solid-organ transplants. While alemtuzumab is not FDA approved for solid-organ transplantation, it is widely recognized as a viable therapeutic option for induction or treatment of acute rejection. In 2012, commercial distribution of alemtuzumab ceased for transplantation and leukemia, requiring centers to enroll in a distribution program for ongoing medication access.

Pharmacology/Mechanism of Action

Alemtuzumab is a humanized monoclonal antibody against the CD52 surface antigen found on both T and B lymphocytes, as well as macrophages, monocytes, eosinophils, and natural killer cells. When alemtuzumab binds to the CD52 surface antigen, antibody-dependent lysis occurs, which removes both T and B lymphocytes from the blood, bone marrow, and organs, resulting in complete lymphocyte depletion.[82]

Pharmacokinetics

The pharmacokinetics of alemtuzumab in solid-organ transplantation patients have not been investigated. In patients with B-cell chronic lymphocytic leukemia, the volume of distribution of alemtuzumab after repeated dosing is 0.18 L/kg. The mean half-life after the first 30 mg dose is 11 hours, but increases to 6 days after 12 weeks of therapy. The extrapolation of these pharmacokinetic data to solid-organ transplantation is difficult because of the differences in dosing strategies used for the FDA indication. One or two doses of alemtuzumab result in complete and prolonged lymphocyte depletion. Following administration, B lymphocyte counts return to normal within 3 to 12 months. T lymphocytes, however, remain depressed for as long as 3 years following administration.[82,83]

Efficacy

Alemtuzumab is effective as induction therapy for the prevention of acute rejection in kidney, liver, heart, pancreas, intestinal, and lung transplants.[84] Additionally, alemtuzumab has been used to successfully treat acute rejection following transplantation and is effective for corticosteroid- and antibody-resistant rejection.[72]

Adverse Effects

Adverse effects of alemtuzumab are primarily infusion-related, hematologic, and infectious. Because alemtuzumab causes complete lymphocyte depletion and associated cytokine release, infusion-related reactions include rigors, hypotension, fever, shortness of breath, bronchospasms, and chills. The potential for developing these reactions can be reduced by administering pre-medications such as acetaminophen, corticosteroids, and diphenhydramine or by administering smaller doses and escalating the dose gradually. Subcutaneous administration may also reduce the incidence of infusion reactions.[85] Hematologic effects include pancytopenia, neutropenia, thrombocytopenia, and lymphopenia.

Drug-Drug and Drug-Food Interactions

No drug or food interactions have been noted with alemtuzumab.

Dosing and Administration

Several dosing regimens have been proposed for alemtuzumab in solid-organ transplantation. The most common dosing strategy is 30 mg administered intravenously or subcutaneously as a single dose; some centers administer a second dose 1 to 5 days after transplantation. Other dosing strategies assessed include 0.3 mg/kg/dose, as a single- or multiple-dose regimen, and, finally, two 20-mg doses given on the day of transplantation and the first postoperative day.[82]

Non-Depleting Antibody Therapy

Basiliximab

Basiliximab, a chimeric monoclonal antibody (25% murine) is the only available IL-2 receptor antagonist currently marketed in the United States. It is approved for use in kidney transplantation but is also extensively used in other organ transplants as well.[86]

Pharmacology/Mechanism of Action

Basiliximab exerts its immunosuppressive effect by specifically binding with high affinity to the α-chain (CD25) on the surface of activated T lymphocytes (see Fig. 109-2). Binding of basiliximab to the IL-2 receptor prevents IL-2-mediated activation and proliferation of T cells, a critical step in clonal expansion of T cells and the development of allograft rejection. Saturation of the IL-2 receptor occurs rapidly and confers an immunosuppressive effect that lasts for 4 to 6 weeks after administration.[86]

Pharmacokinetics

Most of the pharmacokinetic data available for basiliximab was derived following administration to kidney transplant recipients. Caution must be used when extrapolating this information to other transplant recipients. The volume of distribution is approximately 8 L, and it has a half-life of approximately 7 days. Clearance is increased in patients who have received a liver transplant, and it may be necessary in patients with greater than 10 L of ascites to receive an additional dose of basiliximab on postoperative day 8.[87]

Efficacy

Basiliximab is approved for use in kidney transplantation in combination with cyclosporine and corticosteroids, although induction therapy has also been evaluated in liver, lung, and heart transplant recipients. Use of basiliximab in liver transplant recipients has been increasing as a means of delaying CNI initiation in the setting of acute kidney injury.[32,33] A meta-analysis of basiliximab efficacy in kidney transplantation concluded that IL-2 receptor antagonists reduced the risk of rejection with no increases in graft loss, infectious complications, malignancy, or death.[86] Similar results were seen in liver transplant patients.[88]

IL-2 receptor antagonists offer a reasonable addition to calcineurin inhibitor—or corticosteroid-sparing protocols. While CNI therapy cannot be completely avoided in most cases, IL-2 receptor antagonists allow for delayed use or reduced doses of CNIs, thus minimizing the risk of nephrotoxicity in the early post-transplantation period.[33]

Adverse Effects

Relatively few adverse effects have been observed with basiliximab. In contrast to lymphocyte-depleting agents, basiliximab is not associated with infusion-related reactions. However, since the marketing of basiliximab, an increased number of hypersensitivity reactions have been reported. Development of anti-idiotypic antibodies to the murine portion occurs rarely.[88] There appears to be no increased risk of malignancy.

Drug-Drug and Drug-Food Interactions

While cyclosporine and tacrolimus serum concentrations may increase in patients receiving concomitant basiliximab therapy, this interaction is not considered clinically.[86]

Dosing and Administration

Basiliximab is usually administered as two 20-mg intravenous doses, intraoperatively and again on postoperative day 4. Basiliximab is compatible with both 0.9% sodium chloride and 5% dextrose and can be administered either centrally or peripherally over 20 to 30 minutes in a volume of 50 mL.

Other Antibody Therapy

Immune Globulin

Immune globulin (more commonly intravenous immune globulin; IVIG) preparations are derived from human plasma and contain a mixture of antibodies that exert immunomodulatory effects. IVIG is often used prophylactically in solid-organ transplant recipients who are at particularly high risk for antibody-mediated rejection due to the presence of pre-formed DSA at the time of transplant surgery. IVIG may also be used for a variety of other post-transplant complications, including in the management of both cellular and antibody-mediated rejection, hypogammaglobulinemia, and many others that are beyond the scope of this text.

Pharmacology/Mechanism of Action

IVIG is thought to exert its immunomodulatory properties via a number of mechanisms, including inducing B-cell apoptosis and inhibition of complement.[72]

Pharmacokinetics

IVIG has a small volume of distribution (0.05-0.13 L/kg) and upon administration, immune globulin remains primarily in the intravascular compartment. The half-life varies by IVIG preparation but is generally between 14 and 28 days.[89]

Efficacy

When administered to sensitized patients awaiting kidney transplantation, IVIG results in reductions in circulating DSA.[90] Pre-transplant IVIG (in combination with plasmapheresis) provides a mortality benefit owing to dialysis liberation.[91] IVIG leads to similar outcomes compared to anti-CD3 monoclonal antibody (OKT3) in patients being treated for steroid-resistant rejection.[92] IVIG is also often used in the setting of chronic antibody-mediated rejection, though supporting evidence for this practice is lacking.[93]

Adverse Effects

IVIG infusions can be complicated by reactions that include rash, chills, headaches, shortness of breath, or hypotension. For this reason, pre-medications are routinely administered. IVIG has also been known to rarely cause acute kidney injury (more frequently associated with sucrose-containing formulations due to osmotic diuresis), hemolysis, aseptic meningitis, and thromboembolism.[72]

Drug-Drug and Drug-Food Interactions

There are no known drug or food interactions with IVIG.

Dosing and Administration

IVIG doses range from 0.1 to 2 g/kg as either a single dose or doses that are administered sequentially, depending on the indication for use. IVIG infusions should generally begin at slower infusion rates to assess patient tolerability before up-titrating. If IVIG is being administered on the same day as plasmapheresis, it should be administered after immune globulin is removed by pheresis.

Maintenance Agents

The goal of maintenance immunosuppression is to prevent rejection while minimizing drug-related toxicity. As patients progress through the post-transplant course, the risk of acute rejection decreases and the need for pharmacologic immunosuppression is lessened. With few exceptions, maintenance immunosuppression can never be withdrawn following transplantation and thus one or more agents are required lifelong.

Calcineurin Inhibitors

Cyclosporine and tacrolimus are the two calcineurin inhibitors (CNIs) currently used for most solid-organ transplant recipients. More than 90% of transplant recipients receive tacrolimus as part of their immunosuppressive regimen.[94]

Pharmacology/Mechanism of Action

Calcineurin inhibitors block T-cell proliferation by inhibiting the production of IL-2 and other cytokines by T cells (see Fig. 109-2). Cyclosporine and tacrolimus bind to unique cytoplasmic immunophilins: cyclophilin and FK-binding protein-12 (FKBP12), respectively. The drug-immunophilin complex inhibits the action of calcineurin, an enzyme that activates the nuclear factor of activated T cells, which is, in turn, responsible for the transcription of several key cytokines necessary for T-cell activity, including IL-2. IL-2 is a potent T-cell growth factor and ultimately is responsible for activation and clonal expansion.

Pharmacokinetics

The calcineurin inhibitors are highly lipophilic compounds, with variable but generally low bioavailability of approximately 30% (range: 5%-60%). Unlike tacrolimus, cyclosporine depends on bile for intestinal absorption, which further increases inter- and intra-patient variability.

Because of the high variability in absorption of cyclosporine a microemulsion formulation was developed. Both forms are available commercially in the United States and are referred to as “cyclosporine, USP,” and “cyclosporine, USP [MODIFIED].” The two formulations are not bioequivalent and should not be used interchangeably. The modified formulation is self-emulsifying and forms a microemulsion spontaneously with aqueous fluids in the gastrointestinal tract, making it less dependent on bile for absorption. This translates into a greater rate and extent of absorption and decreased intra-individual variability in pharmacokinetic parameters. The relative bioavailability of the microemulsion formulation is 60%, and peak concentrations are reached within 1.5 to 2 hours after oral administration. Tacrolimus, on the other hand, has a more predictable absorption pattern, reaching peak concentrations within 1 to 3 hours with bioavailability of approximately 20%.[95]

Following oral absorption, both cyclosporine and tacrolimus are highly protein bound. Ninety percent of cyclosporine is bound to lipoproteins in the blood while 99% of tacrolimus is bound primarily to plasma proteins, including albumin and α_1-acid glycoprotein, and red blood cells. Cyclosporine is distributed widely into tissue and body fluids, resulting in a large and variable volume of distribution, ranging from 3 to 5 L/kg. Because of the high concentration of FKBP12 that is found in red blood cells, tacrolimus is distributed primarily in the vasculature, with a volume of distribution of 0.8 to 1.9 L/kg. Both drugs are extensively metabolized by the cytochrome P450 3A4 (CYP3A4) in both the gut and the liver, which accounts for their numerous drug interactions that are highlighted in Table 109-5.[83,84,95,96] Cyclosporine and tacrolimus are both excreted primarily in the feces.

Efficacy

Both cyclosporine and tacrolimus are currently approved for prophylaxis of organ rejection in kidney, liver, and heart transplantation. They are both used as primary immunosuppression in lung transplant recipients despite not being approved for this purpose. The microemulsion formulation of cyclosporine has demonstrated equivalent or superior efficacy in kidney, liver, and heart transplantation recipients relative to the non-modified formulation. Tacrolimus and cyclosporine demonstrate equivalent efficacy as primary immunosuppression in regard to overall patient mortality, but tacrolimus is the preferred CNI owing to its superiority in preventing acute rejection.[97]

Adverse Effects

The adverse effects of immunosuppressants are presented in Table 109-6. The nephrotoxic potential of both drugs is equal and is often related to the dose and duration of exposure. Neurotoxicity typically manifests as tremors, headache, and peripheral neuropathy; occasionally, however, seizures have been observed. Tacrolimus may be associated with an increased occurrence of neurologic complications compared with cyclosporine.[97]

TABLE 109-6

Comparison of Common Adverse Effects of Maintenance Immunosuppressants

AZA, azathioprine; Bela, belatacept; CNI, calcineurin inhibitor; CSA, cyclosporine; MPA, mycophenolic acid; mTOR, mammalian target of rapamycin inhibitor; TAC, tacrolimus.

Cyclosporine has a greater propensity to cause hypertension and hyperlipidemia compared with tacrolimus.[98,99] Conversely, hyperglycemia is more common with tacrolimus than with cyclosporine but is often reversible when doses of tacrolimus are reduced.[98] Cyclosporine is associated with cosmetic effects, such as hirsutism and gingival hyperplasia, which may be managed by converting from cyclosporine to tacrolimus. Tacrolimus, in contrast, may cause alopecia, which is usually self-limiting and reversible.

Calcineurin Inhibitor-Associated Nephrotoxicity

Two types of nephrotoxicity can occur with calcineurin inhibitors. Acute nephrotoxicity is seen early and is dose-dependent and reversible, but chronic nephropathy is more problematic. Clinical manifestations of calcineurin inhibitor nephrotoxicity include elevated serum creatinine and blood urea nitrogen concentrations, hyperkalemia, hyperuricemia, proteinuria, and a decreased fractional excretion of sodium. Calcineurin inhibitor nephrotoxicity is the leading cause of impaired kidney function following a non-renal solid-organ transplant, a complication associated with reduced overall patient survival.[100]

The predominant mechanism for calcineurin inhibitor nephrotoxicity is renal vasoconstriction, primarily of the afferent arteriole, resulting in increased renal vascular resistance, decreased renal blood flow by up to 40%, reduced glomerular filtration rate by up to 30%, and increased proximal tubular sodium reabsorption with a reduction in urinary sodium and potassium excretion. A number of other mechanisms have been implicated, including changes in the renin–angiotensin–aldosterone system, prostaglandin synthesis, nitrous oxide production, sympathetic nervous system activation, and calcium handling.[101]

Several approaches have been proposed to reduce calcineurin inhibitor nephrotoxicity, including delaying administration immediately postoperatively in patients at high-risk for nephrotoxicity (using alternative induction protocols including an IL-2 receptor antagonist or antilymphocyte globulin), reducing the calcineurin inhibitor dosage to target lower blood concentrations (if feasible clinically), and avoiding other nephrotoxins (eg, aminoglycosides, amphotericin B, angiotensin-converting enzyme inhibitors and nonsteroidal anti-inflammatory agents) when possible.[101,102] No proven therapies consistently prevent or reverse the nephrotoxic effects of calcineurin inhibitors.

In patients who have received a kidney transplant, it is often difficult to differentiate calcineurin inhibitor nephrotoxicity from kidney allograft rejection. Because the clinical features of acute kidney allograft rejection and calcineurin inhibitor nephrotoxicity overlap considerably, a kidney biopsy is often necessary to differentiate the two (Table 109-7). However, differentiating between chronic kidney allograft rejection and calcineurin inhibitor nephrotoxicity may be more difficult because in addition to clinical signs and symptoms, biopsy findings may also be similar.

TABLE 109-7

Differential Diagnosis of Acute Rejection and Cyclosporine or Tacrolimus Nephrotoxicity

	Nephrotoxicity in Renal Transplant Recipients	
	Acute Rejection	**CSA or TAC Nephrotoxicity**
History	Often <4 weeks postoperatively	Often >6 weeks postoperatively
Clinical presentation	Fever	Afebrile
	Hypertension	Hypertension
	Weight gain	Graft nontender
	Graft swelling/tenderness	Good urine output
	Decreased daily urine volume	
Laboratory biopsy	Rapid rise in SCr	Gradual rise in SCr
	Normal or sub-therapeutic CSA or TAC concentration	Elevated CSA or TAC concentration, especially over long periods of time
	Interstitial lymphocytic infiltrates, peritubular capillaritis, +/- new donor-specific antibodies	Interstitial fibrosis, tubular atrophy, glomerular thrombosis, arterial inflammation

SCr, serum creatinine; CSA, cyclosporine; TAC, tacrolimus.

Drug-Drug and Drug-Food Interactions

Drug interactions occur frequently with the calcineurin inhibitors because they are substrates for CYP3A4 and P-glycoprotein.[83,84,96] The most commonly administered drugs that are known to alter cyclosporine and tacrolimus concentrations are highlighted in Table 109-5. Inhibitors of CYP3A4, such as –azole antifungals protease inhibitors, diltiazem or erythromycin, can increase drug concentrations, whereas drugs that induce CYP3A4 activity, such as phenytoin or rifampin, can decrease drug concentrations.[96]

Cyclosporine, and to a lesser extent, tacrolimus, are inhibitors of CYP3A4 and P-glycoprotein.[95,103] The inhibitory effects of cyclosporine and tacrolimus on CYP3A4 can be seen with weaker substrates, such as the HMG-CoA reductase inhibitors ("statins"). Concomitant administration of a calcineurin inhibitor with an HMG-CoA reductase inhibitor may result in an increase in the HMG-CoA reductase inhibitor concentrations (particularly those metabolized by CYP3A4), which increases the risk of HMG-CoA reductase inhibitor adverse effects, most notably myopathy.[104] Patients should be monitored for clinical signs of myopathy when receiving HMG-CoA reductase inhibitors in combination with cyclosporine and tacrolimus. The interaction appears to be more pronounced between cyclosporine and HMG-CoA reductase inhibitors due to inhibition of organic anion-transporter proteins (OATP) by cyclosporine.[105]

Consistency in the administration of the calcineurin inhibitors with regard to meals and food intake is important to sustain an effective concentration–time profile. High-fat meals can enhance both plasma clearance and the volume of distribution of cyclosporine by more than 60%.[106] Food reduces the rate and extent of tacrolimus absorption, and a high-fat meal may further delay gastric emptying and reduce the maximum achieved serum concentration (C_{max}) and the area under the concentration–time curve (AUC).[95] Furocoumarins such as quercetin, naringin, and bergamottin—found in grapefruit juice—are potent inhibitors of CYP3A4 and may increase both cyclosporine and tacrolimus concentrations. The AUC and C_{max} of cyclosporine may be increased by more than 55% and 35%, respectively.

Dosing and Administration

Initial oral cyclosporine doses range from 6 to 10 mg/kg/day administered in divided doses every 12 hours. Oral tacrolimus doses usually are in the range of 0.1 to 0.3 mg/kg/day in divided doses administered every 12 hours. An extended-release tablet formulation of tacrolimus (Envarsus XR®) has greater bioavailability than the immediate-release formulation and thus a lower recommended daily starting dose (0.14 mg/kg/day).[107] Children often require higher doses to maintain therapeutic drug concentrations, up to 14 to 18 mg/kg/day for cyclosporine and 0.3 mg/kg/day for tacrolimus. Astagraf XL®, another extended-release tacrolimus formulation, and Envarsus XR® are not interchangeable. Astagraf XL® (or Advagraf®) is generally converted from standard tacrolimus formulations on a mg:mg basis whereas Envarsus® XR has greater bioavailability than the immediate release tacrolimus and thus a 20% reduction in total daily dose is recommended.[95,107,108]

If oral administration is not possible, both CSA and TAC can be administered intravenously. Intravenous cyclosporine should be converted at approximately one-third of the total daily oral dosage since administration by this route avoids first-pass metabolism. The usual intravenous dose of cyclosporine is 2 to 5 mg/kg/day, given as a continuous infusion or as a single or twice-daily injection. Intravenous tacrolimus should be converted at approximately one-fourth of the total daily oral dosage, with doses ranging from 0.03 to 0.05 mg/kg/day, and must be administered by continuous infusion.

Therapeutic Drug Monitoring

Calcineurin inhibitors through blood concentrations should be measured routinely to optimize therapy. Both drugs can be measured by radio immunoassay (RIA) or high-performance liquid chromatography (HPLC), which is recognized as the reference procedure.[106] Therapeutic target ranges are assay specific. The specific goal concentration for both drugs is dependent on transplant type, time after transplantation, and concomitant immunosuppression, among other factors. However, target tacrolimus trough concentrations early post-transplantation (ie, 0-3 months) are around 8 to 15 ng/mL (mcg/L; 9.9-18.6 nmol/L) and are reduced over time as clinically tolerated/feasible. Drug concentrations should be measured frequently (daily or three times per week) following initiation of the drug and during the stabilization period after transplantation. With time, blood concentrations can be measured less frequently.

Cyclosporine trough concentrations are poorly predictive of rejection but are the most commonly utilized strategy for therapeutic drug monitoring. In the early post-transplantation period, goal cyclosporine trough concentrations range from 250 to 350 ng/mL (mcg/L; 210-290 nmol/L) and are similarly reduced over time. Alternative strategies, including AUC and peak concentration determination, have been suggested to better correlate with rejection.[106] Limited sampling techniques using two to five blood samples within the first 4 hours after an oral dose have been used to determine AUC and values greater than 4,400 ng/mL/hr correlated with a reduction in rejection.[106,109] Cyclosporine peak concentration (C_{peak}) has also been found to correlate with rejection and toxicity. Some transplantation centers have adopted this strategy to manage cyclosporine concentrations because of the convenience and reduced cost associated with the measurement of a single blood concentration. The suggested therapeutic range for C_{peak} cyclosporine concentrations is 1,500 to 2,000 ng/mL (μg/L; 1,250-1,660 nmol/L) for the first few months after transplant and 700 to 900 ng/mL (μg/L; 580-750 nmol/L) after 6 to 12 months.[106]

Current therapeutic drug monitoring does not ensure complete avoidance of either toxicity or rejection. Intra-patient variability with tacrolimus has been associated with both graft rejection and development of *de novo* donor-specific antibodies. Other measures of CNI exposure such as time in therapeutic range (TTR), commonly employed to measure the adequacy of warfarin monitoring, are positively associated with superior outcomes in lung transplant recipients. Prospective implementation of these findings has not been employed to drive outcomes but may be an opportunity to identify patients at heightened risk for poor outcomes and modify their clinical monitoring.[109–111]

Corticosteroids

Corticosteroids have been used since the beginning of the modern transplantation era. Despite their many adverse events, they continue to be a cornerstone of immunosuppression regimens in many transplant centers.[94] The most commonly used corticosteroids are methylprednisolone and prednisone.

Pharmacology/Mechanism of Action

Corticosteroids block cytokine activation by binding to corticosteroid response elements, thereby inhibiting IL-1, IL-2, IL-3, IL-6, γ-interferon, and tumor necrosis factor-α synthesis. Additionally, corticosteroids interfere with cell migration, recognition, and cytotoxic effector mechanisms.[112]

Pharmacokinetics

Prednisone is converted to prednisolone, its active moiety, in the liver and has multiple effects on the immune system. Prednisone is rapidly absorbed from the GI tract, achieving peak concentrations in 1 to 3 hours in transplant recipients. Bioavailability is greater than 90%. In kidney transplant recipients, the pharmacokinetic half-life is short, 2 to 4 hours, but the pharmacodynamic effects extend beyond the time that concentrations are measurable, permitting daily administration.[112]

Efficacy

The efficacy of corticosteroids is irrefutable based on the decades of clinical experience. Systematic studies comparing corticosteroid-free immunosuppressive agent combinations with conventional therapy are difficult to perform because of the hundreds of potential combinations that now exist. Nevertheless, corticosteroid-free immunosuppressive agent combinations with newer, more specific immunosuppressants hold promise and may be more commonly used in the future.[113]

Adverse Effects

Adverse effects of prednisone that occur in more than 10% of patients include increased appetite, insomnia, indigestion, and mood changes. Side effects that occur less often but which are seen with high doses or prolonged therapy include cataracts, hyperglycemia, hirsutism, bruising, acne, sodium and water retention, hypertension, bone growth suppression, and ulcerative esophagitis. The adverse effects of corticosteroids are summarized in Table 109-6.

Drug-Drug and Drug-Food Interactions

Barbiturates, phenytoin, and rifampin induce hepatic metabolism of prednisolone and thus may decrease the effectiveness of prednisone. Prednisone decreases the effectiveness of vaccines and toxoids.[112]

Dosing and Administration

An intravenous corticosteroid, commonly high-dose methylprednisolone (250-1,000 mg), is given at the time of most solid-organ transplant surgeries and over consecutive days for the treatment of acute rejection. The dose of methylprednisolone is tapered and usually discontinued when oral prednisone is initiated. Prednisone doses are tapered progressively over several weeks to months, as dictated by center-specific protocols. It is preferable to administer corticosteroids in the early morning to mimic the body’s diurnal release of cortisol. Prednisone should be taken with food to minimize GI upset. Abrupt corticosteroid discontinuation is not generally recommendable; tapering should be gradual because of the risk for suppression of the hypothalamic–pituitary–adrenal axis. While conversion to alternate-day regimens or complete withdrawal of prednisone in patients with stable post-transplantation courses has been used with success in some transplantation centers, corticosteroids are often continued for the entire life of the functional graft.[112]

Antimetabolites

Antimetabolites have been used since the early days of transplantation because they prevent the proliferation of lymphocytes. Azathioprine, long considered a part of the "gold standard" regimen with cyclosporine and corticosteroids, has largely been supplanted by mycophenolic acid derivatives which are more specific in their effects on lymphocytes and have fewer side effects.

Mycophenolic Acid Derivatives

Two formulations of mycophenolic acid (MPA) are currently available in the United States: mycophenolate mofetil—the morpholinoethyl ester of MPA —and mycophenolate sodium, which is available as an enteric-coated formulation of the sodium salt of MPA.

Pharmacology/Mechanism of Action

The immunosuppressive effect of MPA is exerted through non-competitive binding to inosine monophosphate dehydrogenase (IMPDH), the key enzyme responsible for guanosine nucleotide synthesis via the de novo pathway. Inhibition of IMPDH results in decreased nucleotide synthesis and diminished DNA polymerase activity, ultimately reducing lymphocyte proliferation.[114] Although MPA inhibits both types of IMPDH: IMPDH I, expressed by all cells in the body, and IMPDH II, which is expressed only in T and B lymphocytes, it is more specific for IMPDH II.[114] T and B lymphocytes only use the de novo pathway for nucleotide synthesis (see Fig. 109-2), making MPA specific for these cells. Other cells within the body have a salvage pathway by which they can synthesize nucleotides, making them less susceptible to the actions of MPA and thereby reducing, but not eliminating, the potential for the hematologic adverse effects seen with azathioprine. In addition to decreasing lymphocyte proliferation, MPA may also downregulate the activation of lymphocytes.[115]

Pharmacokinetics

Because MPA is unstable in an acidic environment, mycophenolate mofetil acts as a prodrug that is readily absorbed from the GI tract, after which it is rapidly and completely converted to MPA by the liver. The enteric coating of mycophenolate sodium protects MPA from the acidic gastric pH and allows MPA to be released directly into the small intestine for absorption. The absolute bioavailability of mycophenolate mofetil and mycophenolate sodium is 94% and 72% of the active moiety, respectively. Peak concentrations of mycophenolate mofetil are reached within 1 to 2 hours following oral administration, while the enteric coating of mycophenolate sodium delays absorption and peak concentrations are not reached until 4 hours after administration.[115]

MPA is extensively bound (97%) to albumin and is eliminated by the kidney and also undergoes glucuronidation in the liver to an inactive glucuronide metabolite (MPAG) that is subsequently excreted in the bile and urine. Enterohepatic cycling of MPAG can lead to deconjugation, thereby recirculating MPA into the bloodstream. This can account for 10% to 60% of total MPA exposure and results in a second peak 6 to 12 hours after oral administration. The half-life of MPA is 18 hours.[115]

Efficacy

Mycophenolate mofetil is approved for use in kidney, liver, and heart transplantation and is recommended as a component of maintenance immunosuppression regimens for most all solid-organ transplant recipients.[61,75] Compared to azathioprine, mycophenolate treatment in patients receiving cyclosporine and corticosteroids leads to a significant improvement in patient and graft survival at 1 and 3 years.[115]

Mycophenolic acid derivatives are a key component of calcineurin inhibitor–sparing protocols. MPA monotherapy has been associated with an unacceptable rejection rate. Combination of MPA with sirolimus, on the other hand, resulted in improved kidney function with no change in acute rejection incidence or patient and graft survival.[115]

Adverse Effects

Unlike cyclosporine and tacrolimus, MPA is not associated with nephrotoxicity, neurotoxicity, or hypertension. The most common side effects are related to the GI tract, including nausea, vomiting, diarrhea, and abdominal pain (see Table 109-6), which occur with similar frequency during intravenous and oral therapy. Strategies to reduce GI symptoms are not well established. Changing formulation may or may not improve symptoms and it is clear that dose reduction and discontinuation increase the risk of rejections.[115] Mycophenolic acid also has hematologic effects, such as leukopenia and anemia, particularly with higher doses, and may be associated with the rare but serious adverse event of progressive multifocal leukoencephalopathy (PML).[115]

Drug-Drug and Drug-Food Interactions

Food has no effect on MPA AUC, but it delays the absorption and decreases MPA C_{max} by 40% and 33% when mycophenolate mofetil and mycophenolate sodium, respectively, are administered. Concomitant administration with aluminum- and magnesium-containing antacids decreases the AUC of MPA, though the significance of this interaction is not likely clinically relevant.[115] Administration of iron may produce similar results, but this has not been tested. Concomitant administration of mycophenolate mofetil with pantoprazole decreases MPA concentrations and systemic exposure in healthy volunteers. The same effect is not observed with mycophenolate sodium. Reduced MPA exposure does not impact graft outcomes in all patients.

Acyclovir, commonly used in kidney transplant recipients for the treatment and prevention of viral infections, competes with MPAG for renal tubular secretion. AUCs of both entities are increased during concomitant acyclovir and MPA administration. No pharmacokinetic interaction with other antiviral agents has been demonstrated; but, there is potential for additive pharmacodynamic effects such as bone marrow suppression.

Decreased MPA trough concentrations are observed when MPA is administered with cyclosporine compared with those achieved when MPA is given with tacrolimus or sirolimus.[115] This interaction is most likely a result of cyclosporine inhibition of multidrug-resistance-associated protein 2 (MRP2), which inhibits the enterohepatic recycling of MPAG, resulting in decreased MPA concentrations.[115] Cyclosporine decreases MPA concentrations by approximately 40% to 50% compared to tacrolimus.[83] To achieve equivalent MPA and MPAG serum concentrations, it may be necessary to administer higher doses of MPA with cyclosporine compared to tacrolimus. Antibiotics may also interfere with enterohepatic recycling of MPAG by decreasing bacterial-mediated de-glucuronidation in the colon.[115] MPA concentrations may also be reduced in the setting of concomitant corticosteroid administration, owing to the induction of glucuronidation caused by steroids.[116]

Dosing and Administration

Mycophenolate mofetil is currently available in both oral and intravenous formulations. Although intravenous administration of equal doses closely mimics oral administration, the two cannot be considered bioequivalent. Mycophenolate sodium is only available as an oral formulation. To optimize immunosuppression and minimize adverse effects, MPA is most commonly administered in two divided doses given every 12 hours. The total daily dose for kidney and liver transplants is typically 2 g/day for mycophenolate mofetil and 1.44 g/day for mycophenolate sodium. The total daily dose in heart transplant recipients is commonly 3 g/day, with a target trough concentration of greater than 1.5 μg/mL (mg/L; 4.7 μmol/L).[61] The recommended pediatric dose is 600 mg/m^2 for mycophenolate mofetil and 400 mg/m^2 for mycophenolate sodium, in two divided doses.

While therapeutic drug monitoring of MPA may be of value it remains controversial.[117–119] Plasma appears to be the most appropriate medium in which to measure MPA for therapeutic drug monitoring, due to the relationship between target plasma MPA concentrations and improved clinical outcomes in patients receiving concomitant CNIs and corticosteroids. For example, patients with trough MPA concentrations between 1.0 and 3.5 μg/mL (mg/L; 3.1-10.9 μmol/L) experience fewer complications. Unbound concentrations as opposed to total MPA concentrations may be the most relevant to measure, especially in patients with liver disease, hypoalbuminemia, and severe infection.[115] Trough concentrations may not be accurate in predicting total drug exposure during a 12-hour interval and thus AUC monitoring has been proposed as the most appropriate measure of MPA drug exposure to guide therapy.[115] Better outcomes are associated with MPA AUC concentrations of greater than 42.8 μg/mL (mg/L; 134 μmol/L) per hour (by HPLC), although a reference range of 30 to 60 μg/mL (mg/L; 94-188 μmol/L) has been proposed.[119] The correlation between MPA AUC values and adverse effects is low. The best means to evaluate MPA concentrations, the acceptable targets for each method, and the appropriate strategy to monitor MPA concentrations remain unclear.[119]

Azathioprine

Azathioprine, a prodrug for 6-mercaptopurine (6-MP), has been used as an immunosuppressant in combination with corticosteroids since the earliest days of the modern transplantation era. Its use has dramatically declined with the availability of newer immunosuppressants, but it remains an option for patients intolerant of other medications.[61,75]

Pharmacology/Mechanism of Action

Azathioprine is an inactive compound that is converted rapidly to 6-MP in the blood and is subsequently metabolized by three different enzymes. Xanthine oxidase, found in the liver and GI tract, converts 6-MP to the inactive final end product, 6-thiouric acid. Thiopurine *S*-methyltransferase (TPMT), found in hematopoietic tissues and red blood cells, methylates 6-MP to an inactive metabolite, 6-methylmercaptopurine. Finally, hypoxanthine-guanine phosphoribosyltransferase is the first step responsible for converting 6-MP to 6-thioguanine nucleotides (6-TGNs), the active metabolites, which are incorporated into nucleic acids, ultimately disrupting both the salvage and de novo pathways of DNA, RNA, and protein synthesis. This process is toxic to the cell and renders the cell unable to proliferate (see Fig. 109-2). Eventually, 6-TGNs are catabolized by xanthine oxidase and thiopurine *S*-methyltransferase to inactive products.[118]

Pharmacokinetics

Oral bioavailability of azathioprine is approximately 40%. Metabolism of 6-MP is primarily by xanthine oxidase to inactive metabolites, which are excreted by the kidneys. The half-life of azathioprine is short, approximately 12 minutes. The half-life of 6-MP is longer, ranging from 0.7 to 3 hours. However, it is the activity of the 6-TGNs that determines the pharmacodynamic half-life of the drug which has been estimated to be 9 days.[120]

Adverse Effects

Dose-limiting adverse effects of azathioprine are often hematologic (see Table 109-6). Leukopenia, anemia, and thrombocytopenia can occur within the first few weeks of therapy and can be managed by dose reduction or discontinuation of azathioprine. Other common adverse effects include nausea and vomiting, which can be minimized by taking azathioprine with food. Alopecia, hepatotoxicity, and pancreatitis are less common adverse effects of azathioprine and are reversible on dose reduction or discontinuation. Activity of TPMT can affect the occurrence of adverse effects with azathioprine. Approximately 10% of the population has intermediate TPMT activity and 0.3% has low activity of the enzyme. In both scenarios, the incidence of leukopenia and hepatotoxicity is increased.

Drug-Drug and Drug-Food Interactions

The xanthine oxidase inhibitors allopurinol and febuxostat increase azathioprine and 6-MP concentrations by as much as fourfold.[120] The metabolic pathways shift to favor the production of 6-TGNs, which ultimately results in increased bone marrow suppression and pancytopenia. Doses of azathioprine should be reduced by at least 50% to 75% when allopurinol is added to a patient's drug regimen.

Dosing and Administration

Usual initial doses of azathioprine range from 1 to 3 mg/kg/day orally. An intravenous formulation exists but is variably available and thus infrequently used in clinical practice.

Mammalian Target of Rapamycin (mTOR) Inhibitors

Two mTOR inhibitors have been approved in the United States for use in transplantation. Sirolimus, also known as rapamycin, is an immunosuppressive macrolide antibiotic that is structurally similar to tacrolimus, and is effective in reducing the risk of acute rejection. Everolimus, a synthetic derivative of sirolimus that was approved in the United States in 2009, was developed to improve upon the pharmacokinetics of sirolimus.

Pharmacology/Mechanism of Action

Sirolimus and everolimus both bind to FKBP12, forming a complex that binds to mTOR, which inhibits the body's response to cytokines (see Fig. 109-2). IL-2 stimulates mTOR to activate kinases that ultimately advance the cell cycle from G1 to the S phase. Thus, these drugs reduce T-cell proliferation by inhibiting the cellular response to IL-2 and progression of the cell cycle.[121,122]

Pharmacokinetics

Bioavailability after oral administration is low for both, only 14% to 20%, with peak concentrations being reached within 1 to 2 hours.[121,122] Both have large volumes of distribution, 5.6 to 16.7 L/kg for sirolimus and between 128 and 529 L for everolimus. Both are metabolized primarily by CYP3A4 in the gut and the liver. Likewise, both are also substrates for P-glycoprotein. The half-life for sirolimus is 60 hours but can be as long as 110 hours in patients with liver dysfunction, while that of everolimus is much shorter (18-35 hours).[121,122]

Efficacy

Sirolimus is approved for the prevention of rejection in kidney transplant recipients when given in combination with corticosteroids and cyclosporine, or after withdrawal of cyclosporine in patients with low-to-moderate immunologic risk. Sirolimus is also effective in combination with tacrolimus or mycophenolate in kidney transplants, with patient survival rates greater than 99% and graft survival rates greater than 96%.[112] Combination therapy with sirolimus and mycophenolate can be used to avoid the use of calcineurin inhibitors and decrease the risk of nephrotoxicity. Everolimus is approved for use in both kidney and liver transplantation. In kidney transplant recipients, it was evaluated in combination with basiliximab, cyclosporine, and corticosteroids, whereas in liver transplant recipients, it was initiated at least 30 days after transplantation in combination with reduced-dose tacrolimus and corticosteroids. Everolimus has also been used with tacrolimus with similar results as sirolimus.[123] Everolimus appears to have less of an effect on wound healing and thus may potentially be used earlier after transplantation.

Early cyclosporine withdrawal has been studied in patients receiving sirolimus-based immunosuppressive protocols. Ideal candidates are patients who have not had a recent or severe rejection episode and have adequate kidney function 3 months after transplant. Rejection occurred in 5.6% of patients after discontinuation of cyclosporine and no difference in graft survival was noted. Long-term follow-up (2 years) showed improved kidney function and blood pressure without an increase in acute rejection or graft loss in patients who discontinued cyclosporine.[112] Similar results have been demonstrated with everolimus.[123]

mTOR inhibitors have demonstrated efficacy to reduce CNI use and nephrotoxicity in liver, heart, and lung transplant patients.[122] mTOR inhibitors have also been investigated in liver transplant patients as a means to reduce the recurrence of hepatitis C and hepatocellular carcinoma.[122] They may also reduce the incidence of chronic rejection after heart transplantation.[65,73]

Adverse Effects

Both everolimus and sirolimus are associated with dose-related myelosuppression. Thrombocytopenia is usually seen within the first 2 weeks of sirolimus therapy but generally improves with continued treatment; leukopenia and anemia are also typically transient.[121,122] Sirolimus trough serum concentrations greater than 15 ng/mL (μg/L; 16 nmol/L) have been correlated with thrombocytopenia and leukopenia.[121] Hypercholesterolemia and hypertriglyceridemia are also common in patients receiving everolimus or sirolimus. The proposed mechanism of this adverse effect is overproduction of lipoproteins or inhibition of lipoprotein lipase. Peak cholesterol and triglyceride concentrations are often seen within 3 months of sirolimus initiation but usually decrease after 1 year of therapy and can be managed by reducing the dose, discontinuing sirolimus, or initiating therapy with an HMG-CoA reductase inhibitor or fibric acid derivative. Dyslipidemia associated with sirolimus may not be a major risk factor for early cardiovascular complications following kidney transplantation.[121] Delayed wound healing and dehiscence could be a result of inhibition of smooth muscle proliferation and intimal thickening.[121] For this reason, mTOR inhibitors are infrequently administered to transplant recipients in the immediate post-operative period. Mouth ulcers are observed in as many as 60% of patients treated with sirolimus and appear to be dose-related.[121] Reversible interstitial pneumonitis has been described in kidney, liver, and heart-lung transplantation recipients.[112] Despite their similarities, everolimus and sirolimus do have some differences likely related to differences in distribution. Sirolimus appears to enhance CSA neurotoxicity and both CSA and TAC nephrotoxicity, whereas everolimus did not.[122] Other adverse effects of sirolimus include increased liver enzymes, hypertension, rash, acne, diarrhea, and arthralgia (see Table 109-6).

Drug-Drug and Drug-Food Interactions

The major metabolic pathway for everolimus and sirolimus is CYP3A4; thus, the drug interactions mediated by induction or inhibition of the CYP3A4 enzyme system are similar to those seen with cyclosporine and tacrolimus (see Table 109-5). Administration of the microemulsion formulation of cyclosporine with sirolimus increases the AUC and trough sirolimus serum concentrations: this has not been observed with the standard formulation of cyclosporine. Conversely, cyclosporine concentrations and AUC are increased when it is given concomitantly with sirolimus. The mechanism is proposed to be competitive binding to CYP3A4 and P-glycoprotein.[121,122] Concomitant administration of tacrolimus does not affect sirolimus concentrations.[121] Although everolimus AUC was increased by the administration of a single dose of the microemulsion cyclosporine formulation, no specific recommendations for dose timing are given. It should be expected, however, that any changes in CSA dose may also necessitate a modification of everolimus dose and increased attention to therapeutic drug monitoring.[121]

As with cyclosporine and tacrolimus, grapefruit juice increases sirolimus concentrations. Administration of sirolimus with a high-fat meal is associated with a delayed rate of absorption, decreased C_{max}, and increased AUC, indicating an increased drug exposure, whereas the half-life remains unchanged.[121] Conversely, administration of everolimus with a high-fat meal was associated with decreases in both C_{max} and AUC.[122]

Dosing and Administration

The fixed sirolimus dosing regimen, approved for concomitant use with cyclosporine, includes a loading dose of 6 to 15 mg followed by 2 or 5 mg daily, respectively. However, loading doses are no longer recommended in clinical practice due to an increase in side effects. Therapeutic monitoring of sirolimus is routinely performed using whole-blood concentrations measured by HPLC, which is specific for the parent compound. For everolimus, a starting dose of 0.75 mg twice daily is indicated in regimens that contain cyclosporine, corticosteroids, and basiliximab induction. Target serum concentrations are 3 to 8 ng/mL (mcg/L; 3.1-8.4 nmol/L).

Co-Stimulatory Signal Inhibitor

Belatacept, derived from abatacept, is the only drug currently approved for use in solid-organ transplantation in this class of immunosuppressive agents. Belatacept may ultimately replace calcineurin inhibitors in the majority of immunosuppressive regimens given the lack of toxicities frequently seen with CNIs, especially nephrotoxicity.[23] Belatacept is only approved for kidney transplantation.

Pharmacology/Mechanism of Action

Belatacept is a selective co-stimulation blocker that binds co-stimulatory ligands (CD80 and CD86) on antigen-presenting cells, preventing interaction with CD28 on T cells (see Fig. 109-2). The interaction of CD80 and CD86 with CD28 is required for the initiation of “signal 2,” the co-stimulatory signal that produces calcineurin, protein kinases, and nuclear factor-κ β that lead to the activation and proliferation of T-cells. Thus, blockade of CD80 and CD86 prevents T-cell activation.[124]

Pharmacokinetics

Belatacept, which is only available as an intravenous formulation, has a volume of distribution of 0.11 L/kg, a half-life of approximately 11 days and is not affected by impaired kidney or liver function.

Efficacy

Belatacept and cyclosporine exhibit similar efficacy in terms of both patient and graft survival in first time kidney transplant recipients. Cyclosporine users experienced more chronic allograft nephropathy at month 12, while the belatacept users experienced more frequent and more severe ACR. Despite this, the measured GFR was 13 to 15 mL/min (0.22-0.25 mL/s) higher in the belatacept group compared to the cyclosporine group, a trend that persisted for 7 years.[125] Additionally, belatacept-treated patients had better blood pressure control and lower lipid concentrations as well as less diabetes than CNI-treated patients. This finding may underlie the mortality difference observed at 7 years of follow-up.[23] Compared to tacrolimus, ACR is more common among kidney transplant recipients receiving belatacept whereas the incidence of metabolic and neurologic toxicities is less common.[126] Conversion from CNI-based regimens to belatacept in kidney transplant recipients with stable kidney function leads to improved GFR from baseline.[127,128] However, acute rejection occurs more frequently in patients who switch to belatacept, compared with no acute rejection in the patients who remain on CNI.[23]

Use of belatacept in liver transplant patients has been associated with increased graft loss and death.[36,124] There is limited post-marketing experience with belatacept in heart and lung transplant recipients, though this is an area of ongoing interest.[127,129]

Adverse Effects

Belatacept is generally well tolerated. Adverse effects among belatacept recipients include anemia, neutropenia, diarrhea, urinary tract infections, headache, and peripheral edema.[23] Patients who are Epstein Barr virus (EBV) naïve experienced a higher incidence of post-transplant lymphoproliferative disease (PTLD). PTLD typically occurs within the first 18 months of treatment and the majority occur in the central nervous system. There was no increase in incidence of PTLD in patients who are EBV-seropositive. As a result, belatacept carries a boxed warning for PTLD and is contraindicated in patients who are EBV-seronegative. Belatacept has been associated with progressive multifocal leukoencephalopathy (PML).[23]

Drug-Drug and Drug-Food Interactions

There are no known drug or food interactions with belatacept.

Dosing and Administration

Potential belatacept recipients must be screened for EBV-serostatus prior to initiation of therapy. Only patients who are EBV-seropositive should receive belatacept due to the increased risk of PTLD in EBV-seronegative patients. As a primary immunosuppressant for first time kidney transplants, belatacept is administered as 10 mg/kg intravenously over 30 minutes on days 0, 4, 14, 28, and at the end of weeks 8 and 12. Thereafter, the dose is reduced to the maintenance dose of 5 mg/kg administered IV over 30 minutes every 4 weeks beginning at week 16.

When converting to belatacept from a CNI-based regimen, the proposed dosing schedule is 5 mg/kg IV administered every 2 weeks for 5 doses on days 0, 14, 28, 42, and 56, then every 4 weeks thereafter. The CNI dose should be decreased by 50% after the second dose of belatacept and then discontinued after the fourth dose.[23]

Investigational Agents

Rituximab

Rituximab is a chimeric monoclonal antibody against the CD20 receptor found on selected populations of B cells. While it is FDA approved for non-Hodgkin lymphoma and rheumatoid arthritis, it has also been used for the treatment and prevention of antibody-mediated rejection and post-transplant lymphoproliferative disorders.[130] In highly sensitized patients, rituximab administration prior to transplant suppresses alloantibody levels.[131] However, when used in kidney transplant recipients with active AMR, administration of rituximab has failed to consistently demonstrate efficacy.[132] In PTLD, rituximab is most effective in patients with CD20-positive malignancies.[130]

Bortezomib

Bortezomib, a proteosomal inhibitor that is FDA approved for the treatment of multiple myeloma, has been used in the treatment of AMR. Among patients with AMR who received four doses of bortezomib 1.3 mg/m^2 on days 1, 4, 7, and 11 with plasmapheresis, bortezomib was effective in lowering DSA by 50%.[72] Another series showed a benefit of bortezomib over rituximab.[72] However, bortezomib is associated with a high incidence of side effects (up to 33% required hospitalization) that may include diarrhea/dehydration, nausea, edema, thrombocytopenia, infections, and peripheral neuropathy.[72]

EVALUATION OF THERAPEUTIC OUTCOMES

The success of transplantation can be measured in terms of length of graft and patient survival as well as improvements in quality of life. Several donor and recipient factors that have an impact on graft and patient survival have been identified. The greatest risks to short-term graft survival are technical/surgical complications and acute rejection. Routine surveillance of appropriate biochemical markers and serum drug concentrations is essential to minimize the potential for acute rejection. These parameters should be assessed daily to weekly for the first 1 to 3 months after transplantation.

Monitoring for recipients of all solid-organ transplants should include complete blood counts, serum electrolyte concentrations, serum creatinine and blood urea nitrogen concentrations, and the appropriate serum drug concentrations. Liver function tests should also be evaluated using the same schedule in liver transplantation recipients. Routine biopsies are necessary to monitor for acute rejection in lung and heart transplantation recipients. As the time after transplantation increases, the frequency of monitoring decreases. Once 3 months have elapsed after transplantation, monitoring of these parameters can be reduced to biweekly or monthly for most patients. Table 109-8 depicts a typical post-transplantation laboratory monitoring plan. Long-term graft survival of all solid-organ transplants is limited by chronic rejection, a complication with few effective therapies which often necessitates re-transplantation.

TABLE 109-8

Laboratory Monitoring After Transplantation

	1-2 Weeks	1 Month	2-4 Months	4-12 Months	>12 Months
SCr/BUN	Daily	1-2 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Chemistries[a]	Daily	1-2 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Liver function tests[b]					
Kidney or heart recipient	Once	Once	Monthly	Every 1-3 months	Every 1-3 months
Liver recipient	Daily	1-3 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Immunosuppressant concentrations	Daily	1-2 times per week	Every 1-2 weeks	Monthly	Every 1-2 months
Complete blood count[c]	Daily	1-2 times per week	Every 1–2 weeks	Monthly	Every 1-2 months
Lipid panel[d]	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months
HbA_{1c}	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months

BUN, blood urea nitrogen; HbA_{1c}, hemoglobin A1c; SCr, serum creatinine.

[a] Chemistries include sodium, potassium, chloride, CO_2 content, magnesium, calcium, phosphorus, and blood glucose.

[b] Liver function tests include total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), gamma glutamyl transpeptidase (GGTP), alkaline phosphatase.

[c] Complete blood count includes white blood cells (WBC), red blood cells (RBC), platelets, +/- differential.

[d] Lipid panel includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), and triglyceride

IMMUNOSUPPRESSION-RELATED COMPLICATIONS

A fine counterbalance exists between under and over-immunosuppression. Beyond the first year post-transplant, death with a functioning graft is mostly attributed to cardiovascular disease, infection, and malignancy.[133] CNIs and corticosteroids, mainstays of maintenance immunosuppression, both contribute to cardiovascular disease-related risk factors including new-onset hypertension, diabetes, hyperlipidemia, and chronic kidney disease. All immunosuppressive agents inherently increase the risk of infection and impair cancer-related surveillance, which may lead to either de novo cancer post-transplant or cancer recurrence.[134] Routine surveillance including assessment and treatment of cardiovascular risk factors, along with vaccinations and age-appropriate cancer screening, are vital to ensure long-term patient survival. The following sections will review immunosuppression-related complications including cardiovascular disease, infections, and malignancy.

Cardiovascular Disease

Cardiovascular disease is a leading cause of morbidity and mortality in transplant patients.[135] Hypertension, hyperlipidemia, and diabetes are common complications in transplanted recipients and are independent risk factors for cardiovascular disease.

Hypertension

Corticosteroids, tacrolimus, cyclosporine, and impaired kidney graft function may all contribute to post-transplantation hypertension. Calcineurin inhibitor-associated hypertension may be due to increased endothelin production as well as stimulation of the sympathetic and renin-angiotensin systems.[136] In addition to the propensity to cause peripheral vasoconstriction, CNIs promote sodium retention, resulting in extracellular fluid volume expansion. Tacrolimus appears to have less potential to induce hypertension following transplantation than cyclosporine.[99,136,137]

Dihydropyridine calcium channel blockers have traditionally been the first-line agents to treat hypertension after transplantation.[136] They may ameliorate the nephrotoxic effects of CNIs and improve renal hemodynamics.[138] ACEIs and angiotensin II receptor blockers have traditionally been avoided in kidney transplantation recipients, especially in the perioperative period, because of the potential for hyperkalemia and negative influence on glomerular filtration rate. When ACEIs or angiotensin II receptor blockers are used in patients after transplant, serum creatinine and potassium concentrations should be monitored closely. If the increase in serum creatinine is greater than 30% within 1 to 2 weeks after initiating ACEIs or angiotensin II receptor blockers, other alternatives must be considered (see Chapter 65).

Multiple antihypertensive agents are usually necessary to achieve the goal of blood pressure in transplant recipients; consequently, the addition of a *β*-blocker, diuretic, or centrally acting antihypertensive may also be necessary. Calcineurin inhibitor-induced hypertension is often salt-sensitive, making it responsive to diuretics. Central-acting agents (eg, clonidine) are used often as adjunctive therapy in transplantation recipients who are unable to achieve blood pressure control with first-line pharmacotherapy agents. There are no universal goals for blood pressure in transplant recipients. Most indicate a goal between 130-140/80-90 depending on other compelling co-morbid disease states.[136]

Hyperlipidemia

Hyperlipidemia may be exacerbated by corticosteroids, calcineurin inhibitors, and mTOR inhibitors.[74,75] Corticosteroids promote insulin resistance and a decrease in lipoprotein lipase activity, as well as excessive triglyceride production. CNIs may decrease the activity of the low-density lipoprotein (LDL) receptor or lipoprotein lipase, altering LDL catabolism.[74] Tacrolimus appears to have less potential than cyclosporine to induce hyperlipidemia.[99] Controversy remains whether the management of hyperlipidemia in transplant recipients should be more aggressive than current guidelines for the general population (see Chapter 32).[75,139] Aggressive lipid lowering may not only arrest the progress or prevent the complications of atherosclerosis but may also promote graft survival in kidney and heart transplant recipients. Current recommendations suggest monitoring lipid panels 2 to 3 months after transplantation and annually thereafter.[61,75]

HMG-CoA reductase inhibitors should be used with caution in transplantation recipients because of the risk of rhabdomyolysis when these agents are combined with CNIs.[104] However, beyond their impact on hyperlipidemia, HMG-CoA reductase inhibitors also have immunomodulatory effects on MHC expression and T-cell activation, and they reduce cardiac allograft rejection and extend life in heart transplant recipients.[104]

Concurrent use of simvastatin and cyclosporine is contraindicated due to the increased risk of rhabdomyolysis.[139] The concurrent use of medications known to increase the risk of myopathy (such as gemfibrozil) should be avoided.[104] Baseline and follow-up creatinine phosphokinase measurements (every 6 months) have proven useful in identifying patients with subclinical rhabdomyolysis. HMG-CoA reductase inhibitors not metabolized by CYP3A4 may be preferred owing to their diminished risk of CNI-associated drug-drug interactions. Close monitoring of liver function is recommended in all transplant recipients.[75,139]

For transplant patients who have hypertriglyceridemia refractory to dietary intervention, fish oil and fibric acid derivatives are generally well-tolerated, effective alternatives (see Chapter 32). Fibric acid derivatives are most effective in lowering serum triglyceride concentrations. The novel PCSK9 inhibitors have been used in heart transplant recipients who are intolerant to HMG-CoA reductase inhibitors or those who require further LDL lowering therapy, but evidence to support this practice in other solid-organ transplant recipients is lacking.[140]

Post-Transplantation Diabetes Mellitus

Corticosteroids and CNIs can impair glucose control in patients with pre-existing diabetes and may cause post-transplantation diabetes mellitus (PTDM) in 5% to 30% of solid-organ transplant recipients.[70,75,98] Corticosteroids induce insulin resistance and impair peripheral glucose uptake, whereas CNIs appear to inhibit insulin production.[74] Tacrolimus seems to be more diabetogenic than cyclosporine.[99] Other possible risk factors that have been identified for PTDM include African American race or Hispanic ethnicity, age greater than 40 years at time of transplant, family history, and obesity, as well as CMV and Hepatitis C virus infection.[74]

Up to 40% of patients with PTDM will require insulin therapy.[74] In patients with post-transplant diabetes who can be adequately managed with only oral hypoglycemics, agents such as dipeptidyl peptidase 4 (DPP-4) inhibitors, thiazolidinediones (TZDs), and sulfonylureas may be reasonable choices. Agents that do not undergo extensive renal elimination may be preferred to reduce the incidence of hypoglycemia and toxicity in the setting of drug accumulation due to end-organ dysfunction. Metformin should be used with caution because of the risk of lactic acidosis in those with impaired kidney function but is generally well-tolerated and may be associated with improved long-term outcomes.[141] Short-term use of SGLT2 inhibitors has been endorsed in transplant patients.[142]

Frequent blood glucose monitoring is imperative in the early postoperative phase to improve glucose control and to identify those with PTDM. Changes in kidney function secondary to CNI-associated nephrotoxicity, acute rejection, or other causes in kidney transplant recipients affectis elevated without the elimination of many hypoglycemic agents, including insulin, and may result in hyper- or hypoglycemia. Dose changes of immunosuppressant drugs also affect glycemic control. Tapering of immunosuppressive medications may result in reduced insulin requirements, whereas corticosteroid pulses for the treatment of rejection may result in increased insulin requirements.

Infection

Increased risk of infection is a natural consequence of pharmacologic immunosuppression. Many infections in solid-organ transplant recipients, including cytomegalovirus and fungal infections, are reviewed in Chapter 145.

Polyomavirus-associated nephropathy (PVAN) is an important cause of impaired kidney function in kidney transplant recipients.[143] Primary infection with BK virus occurs in childhood as an asymptomatic infection in 50% to 90% of the general population. The precise mechanism of transmission is not clear but is suspected to be via the oral or respiratory routes. The virus may remain latent primarily in the genitourinary tract until reactivation as the result of compromised immune function. Reactivation can be detected by measuring the presence of BK virus in the urine or plasma, a finding that is seen in approximately 30% to 40% of kidney transplant recipients, although it does not progress to nephropathy in the majority of patients. However, BK viremia (if it develops) has been noted to progress to allograft nephropathy in 50% of patients.[143] The development of BK virus nephropathy results in graft loss in about 46% of affected patients.[143]

All kidney transplant recipients should be screened for urinary BK virus replication monthly for the first 3 to 6 months after transplant, and every 3 months thereafter for the first year.[75,143] Screening for BK virus in serum should also occur any time the serum creatinine is elevated without a known cause and after treatment of acute rejection. Treatment of BK virus should be initiated when plasma concentrations persist above 10,000 copies/mL (10×10^6/L).[75,143] The first line of treatment is to reduce immunosuppressive medications, targeting tacrolimus trough concentrations of <6 ng/mL (mcg/L; 7.4 nmo/L), cyclosporine <150 ng/mL (mcg/L; 125 nmol/L), sirolimus troughs <6 ng/mL (mcg/L; 6.6 nmol/L) or total daily mycophenolate mofetil doses of <1,000 mg. Other treatment strategies may include the addition of cidofovir, leflunomide, or fluoroquinolones.[143]

Malignancy

Although advances in immunosuppression have decreased the incidence of acute rejection and increased patient survival, they have also increased the solid-organ transplant recipients' lifetime exposure to immunosuppression. While the precise mechanism is unclear, post-transplantation malignancy seems to be related to the overall level of immunosuppression, as evidenced by a difference in the rates of malignancy associated with quadruple versus triple versus dual immunosuppressant regimens. The risk of *de novo* malignancy in transplantation recipients is increased threefold to fivefold relative to the general population, and the risk of lung and colon cancers may be as much as doubled in kidney transplant recipients.[115,144] A number of cancers that are uncommon in the general population occur with much higher prevalence in transplantation recipients: post-transplantation lymphomas and lymphoproliferative disorders (PTLD), Kaposi sarcoma, renal carcinoma, in situ carcinomas of the uterine cervix, hepatobiliary tumors, and anogenital carcinoma are a few examples.[144]

Skin cancers are the most common tumors. Factors that may predispose transplant recipients to skin cancers include sun exposure, the use of immunosuppressive medications, and concomitant use of medications that increase the risk of phototoxicity.[145] The mTOR inhibitors have a theoretical benefit in reducing the development of malignancy by way of antiproliferative effects. In fact, a decreased incidence of malignancy may be observed in patients receiving mTOR inhibitors versus CNIs, and conversion to mTOR inhibitors may result in regression of Kaposi sarcoma.[144]

PTLD encompasses a broad spectrum of disorders, ranging from benign polyclonal hyperplasia to malignant monoclonal lymphomas. Factors that predispose patients to PTLD include Epstein-Barr virus seronegativity at transplantation and intense immunosuppression, particularly with lymphocyte-depleting agents. Non-renal transplantation recipients are more likely to develop PTLD secondary to the intensive immunosuppression used to reverse rejection. Treatment of life-threatening PTLD generally includes severe reduction or cessation of immunosuppression. Other options include systemic chemotherapy or rituximab.[144]

Post-transplantation malignancies appear at an average of 5 years after transplantation and their incidence increases with the increasing length of follow-up. As many as 72% of solid-organ transplant recipients surviving greater than 20 years may be affected. Malignancy accounts for 11.8% of deaths after cardiac transplantation and is the single most common cause of death in the 6th to the 10th post-transplant years.[144]

CLINICAL BOTTOM LINE

Transplantation is a lifesaving therapy for several types of end-organ failure. Advances in the understanding of transplant immunology have produced an unprecedented number of choices in terms of immunosuppression. The increasing number of effective immunosuppressive therapies offers clinicians diverse ways to prevent allograft rejection.

However, the vast array of currently available immunosuppressive agents make it increasingly difficult to evaluate their long-term efficacy. Clinicians must be keenly aware of the adverse effects of immunosuppressive medications and their management in order to optimize the care of the transplanted patient.

ABBREVIATIONS

ACEI	angiotensin-converting enzyme inhibitor
ACR	acute cellular rejection
AMR	antibody-mediated rejection
APC	antigen-presenting cell
ATG	antithymocyte globulin
ATN	acute tubular necrosis

AUC	area under the concentration curve
C_2	concentration 2 hours after dose
C_{peak}	peak concentration
CI	calcineurin inhibitors
CMV	cytomegalovirus
CYP	cytochrome P450 liver enzyme system
DAA	direct acting antivirals
DGF	delayed graft function
EBV	Epstein Barr virus
ESKD	end-stage kidney disease
FKBP	FK506-binding protein
GI	gastrointestinal
HBIg	hepatitis B immunoglobulin
HLA	human leukocyte antigen
HMGCoA	hydroxy-3-methylglutaryl-coenzyme A
HPLC	high-performance liquid chromatography
IFN	interferon
IFTA	interstitial fibrosis and tubular atrophy
IL-2R	Interleukin 2 receptor
IMPDH	inosine monophosphate dehydrogenase
LAS	lung allocation score
LDL	low-density lipoprotein
MELD	model for end-stage liver disease
MHC	major histocompatibility complex
6-MP	6-mercaptopurine
MPA	mycophenolic acid

MPAG	mycophenolic acid glucuronide
MRP2	multidrug-resistance-associated protein 2
mTOR	mammalian target of rapamycin
NFAT	nuclear factor of activated T lymphocytes
NODAT	new-onset diabetes after transplantation
OATP	organic anion-transporter proteins
OKT3	muromonab-CD3
PD-L1	programmed death ligand 1
PML	progressive multifocal leukoencephalopathy
PRA	panel of reactive antibodies
PSI	proliferation signal inhibitor
PTLD	post-transplantation lymphoproliferative disorder
PVAN	polyomavirus associated nephropathy
RIA	radioimmunoassay
REMS	risk evaluation and mitigation strategy
TPMT	thiopurine S-methyltransferase

SELF-ASSESSMENT QUESTIONS

1. Which of the following is NOT true regarding induction immunosuppression strategies?

   A. They are used patients at high risk of rejection.

   B. They are used to delay the initiation of nephrotoxic medications.

   C. They refer to use of antibody agents.

   D. They include calcineurin inhibitors.

2. Which class of medications should be given to all heart transplant recipients in order to prevent/mitigate the development of chronic rejection (ie, coronary allograft vasculopathy)?

   A. HMG-CoA reductase inhibitors (ie, statins)

   B. Bile acid sequestrants

   C. Fibrates (eg, gemfibrozil)

   D. PCSK9 inhibitors

3. A 48-year-old male received a heart transplant 6 months ago. He has preexisting kidney impairment, hypertension (BP = 160/95) and hyperlipidemia. His most recent heart biopsy showed no signs of rejection. His current immunosuppressant regimen is: tacrolimus 3 mg by mouth twice a day (last concentration 11 ng/mL [mcg/L; 13.6 nmol/L]), mycophenolate mofetil 1,000 mg by mouth twice daily and prednisone 5 mg by mouth daily. Which of the following is true?

   A. Replacing tacrolimus with everolimus may improve his hypertension and hyperlipidemia

   B. Replacing tacrolimus with sirolimus may improve his kidney function and hypertension

   C. Replacing tacrolimus with cyclosporine may improve his hypertension and kidney function

   D. Replacing tacrolimus with sirolimus may improve his kidney function and hemoglobin

4. A 34-year-old female kidney transplant recipient is receiving an immunosuppressant regimen consisting of tacrolimus and mycophenolate mofetil. She is 3 months post-transplant and has stable kidney function. She is complaining of excessive hair loss. What change might the clinician consider?

   A. Change mycophenolate to azathioprine

   B. Change tacrolimus to either cyclosporine or belatacept

C. Add everolimus to her regimen

D. Add belatacept to her regimen

5. Which of the following immunosuppressants has the longest half-life?

A. Cyclosporine

B. Tacrolimus

C. Prednisone

D. Sirolimus

6. A 47-year-old, 70-kg lung transplant recipient is currently receiving the following medications: tacrolimus, mycophenolate mofetil, sirolimus, prednisone, valganciclovir, sulfamethoxazole-trimethoprim thrice weekly and nystatin. His most recent laboratory evaluation revealed: WBC 2,100/mm^3 (2.1 × 10^9/L) Hgb 11.8 g/dL (118 g/L; 7.32 mmol/L), SCr 1.3 mg/dL (115 μmol/L), and tacrolimus 11 ng/mL (mcg/L; 13.6 nmol/L). Which of the following is NOT likely contributing to his leukopenia?

A. Mycophenolate mofetil

B. Sirolimus

C. Tacrolimus

D. Valganciclovir

7. Which of the following immunosuppressive medication is most likely to have increased AUC during treatment of esophageal candidiasis infection with fluconazole?

A. Cyclosporine

B. Prednisone

C. Mycophenolic Acid

D. Belatacept

8. A 57-year-old male with a kidney transplant is diagnosed with post-transplant BK nephropathy. His current immunosuppressant regimen consists of: tacrolimus 6 mg by mouth twice daily and sirolimus 3 mg by mouth daily. Which of the following changes should the clinician consider?

A. Increase sirolimus dose/trough goal

B. Change sirolimus to mycophenolate

C. Decrease tacrolimus dose/trough goal

D. Change tacrolimus to belatacept

9. Which of the following statements is true?

A. Tacrolimus increases MPA concentrations due to interference with enterohepatic recycling of MPAG.

B. Febuxostat inhibits xanthine oxidase, the enzyme responsible for elimination of MPAG.

C. Phenytoin decreases tacrolimus concentrations by inducing activity of CYP 3A4 enzymes.

D. Magnesium-containing antacids cannot be used concurrently with azathioprine.

10. A 42-year-old female is being discharged after receiving a heart transplant 2 weeks ago. Which of the following is NOT an appropriate monitoring plan for the next month?

    A. Serum creatinine should be monitored once or twice a week.

    B. Liver function tests should be monitored once or twice a week.

    C. Tacrolimus concentrations should be monitored once or twice a week

    D. Complete blood counts should be monitored monthly.

11. A 32-year-old male received a kidney transplant 3 weeks ago secondary to type I diabetes. He presents to clinic with a blood pressure of 160/98 and HR 62. He is afebrile. Recent laboratory values include Scr 1.1mg/dL (97 µmol/L) (nadir 1.0 mg/dL [88 µmol/L]), potassium 4.1 meq/L (mmol/L), WBC 4,100/mm^3 (4.1 × 10^9/L). His current medications include tacrolimus 8 mg twice daily (trough 9.8 ng/mL [mcg/L; 12.2 nmol/L]) and mycophenolate sodium 720 mg twice daily. Choose the most appropriate antihypertensive agent to initiate.

    A. Amlodipine

    B. Diltiazem

    C. Lisinopril

    D. Metoprolol

12. Which of the following statements regarding belatacept is true?

    A. There are both immediate and extended release formulations.

    B. Patients who are EBV seropositive are ineligible for treatment with belatacept

    C. Belatacept is used in immunosuppressive regimens in combinations with other immunosuppressants, such as CNI, antimetabolites, mTOR inhibitors, and/or corticosteroids

    D. Belatacept is used as single-agent immunosuppression

13. A 58-year-old liver transplant recipient presents to the transplant clinic with a blood glucose log that she has been keeping at home, which indicates a new diagnosis of post-transplant diabetes. Which of the following statements is true regarding initiation an anti-hyperglycemic agent in a solid-organ transplant recipient?

    A. Metformin should be avoided due to risk for lactic acidosis.

    B. Dipeptidyl-peptidase 4 inhibitors are often used as first-line therapy for patients who are candidates for oral anti-hyperglycemic treatment.

    C. Insulin should be the first anti-hyperglycemic agent selected for all solid-organ transplant recipients owing to its unlimited efficacy and titratable dosing.

    D. Very few antihyperglycemic agents are renally excreted and thus it is generally not necessary to evaluate for end-organ function prior to selecting an agent.

14. A 46-year-old lung transplant recipient presents to the transplant clinic complaining of new onset shortness of breath. Her current immunosuppressive medications include tacrolimus (goal 8-10 ng/mL [mcg/L; 9.9-12.4 nmol/L]), mycophenolate 250 mg twice daily, and prednisone 5 mg daily. Bronchoscopy and transbronchial biopsy are performed confirming mild cellular rejection. Which of the following is the most appropriate pharmacotherapy plan?

A. Methylprednisolone pulse followed by taper

B. Methylprednisolone pulse followed by taper with a simultaneous increase in mycophenolate dose, targeting 1000 mg twice daily

C. Antithymocyte globulin 7.5 mg/kg over 5 to 7 days

D. Rituximab 375 mg/m^2 ×1 dose

15. Which of the following statements are false regarding the use of mTOR inhibitors in solid-organ transplant recipients?

A. They are only approved for use in liver transplant recipients who have new-onset kidney disease post-transplant.

B. They are susceptible to drug interactions if used concurrently with CYP 3A4 inhibitors/inducers.

C. They require therapeutic drug monitoring.

D. They are difficult to tolerate owing to a multitude of potential ADEs.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Calcineurin inhibitors are not used for induction immunosuppression. These agents are given as part of maintenance immunosuppression (long-term).

2. **A.** The statin medications have been shown to prevent coronary allograft vasculopathy in several well-designed clinical trials. As such, these agents should be given to all heart transplant recipients. The other choices have not proven effective in preventing CAV.

3. **B.** Replacing tacrolimus with sirolimus would reduce the risk of renal injury and hypertension that are both common side effects of tacrolimus. The other choices are not correct because the changes to the medication regimen suggested are not correctly matched with side effects of the respective drugs involved in the swap.

4. **B.** Alopecia is a known side effect of tacrolimus; however it is not associated with the use of either cyclosporine or belatacept. The possible benefits should be cautiously weighed against the risks of converting to either a belatacept- or cyclosporine-based immunosuppression regimen. Refer to Table 6 for further study of drug-related ADE.

5. **D.** Sirolimus has the longest half-life of the available options (60-110 hours).

6. **C.** Leukopenia is a common side effect of mycophenolate, sirolimus, as well as valganciclovir. Tacrolimus is rarely implicated in hematologic disturbances. Refer to Table 6 for further study of drug-related ADE.

7. **A.** Cyclosporine is a substrate of CYP 3A4, and therefore, the exposure will increase with concomitant use of fluconazole (CYP 3A4 inhibitor). Prednisone, mycophenolic acid, or belatacept are not metabolized via CYP 3A4.

8. **C.** As with most post-transplant opportunistic infections, a mainstay of management involves some reduction in net immunosuppression. Neither the substitution of mycophenolate for sirolimus or belatacept for tacrolimus would be beneficial in the setting of BK nephropathy.

9. **C.** Phenytoin is an inducer of CYP 3A4 and therefore decreases the serum concentrations of tacrolimus. See Table 5 for further study.

10. **D.** Once a patient is discharged two weeks after transplant, weekly monitoring is required for some time. As such, choice D is not correct, as waiting one month to follow up on the patient is not safe.

11. **A.** Dihydropyridine calcium channel blockers (DHP CCB) are routinely used as first line antihypertensive agents in solid-organ transplant recipients. Nodal blocking agents (eg, metoprolol or non-DHP CCB) would not be advised in this patient with baseline HR of 62 bpm, and initiating lisinopril may lead to an acute rise in serum creatinine that may require evaluation for acute rejection, technical/surgical complications, or other causes of posttransplant acute kidney injury.

12. **C.** Belatacept is available exclusively for intravenous administration, is not to be used in EBV seronegative patients due to the risk for post-transplant lymphoproliferative disease, and is not recommended for use as monotherapy.

13. **B.** Choice A is incorrect because while lactic acidosis is a concern in post-transplant recipients, the risk is minimal and metformin is often used. Choice D is also incorrect as many anti-hyperglycemic agents are renally excreted. Although patients may be started on insulin, it is not universally considered first line, therefore Choice B is correct.

14. **B.** For mild cellular rejection, treatment with high-dose IV cortico-steroids and simultaneous increase in background maintenance immunosuppression is warranted. If sub-optimal response is achieved, more intensive therapies may be considered thereafter. Refer to Fig. 109-3 for general approach to management of post-transplant rejection.

15. **A.** Choice A is false because mTOR inhibitors have several indications related to solid-organ transplantation.

Chapter 110: Osteoarthritis

Lucinda M. Buys; Sara A. Wiedenfeld

KEY CONCEPTS

KEY CONCEPTS

① Osteoarthritis (OA) is a common disease. OA prevalence increases with age and number of other chronic conditions, with women more commonly affected than men.

② Contributors to OA are systemic (age, genetics, hormonal status, obesity, occupational or recreational activity) and/or local (injury, overloading of joints, muscle weakness, or joint deformity).

③ OA is primarily a disease of cartilage that reflects a failure of the chondrocyte to maintain proper balance between cartilage formation and destruction. This leads to loss of cartilage in the joint, local inflammation, pathologic changes in underlying bone, and further damage to cartilage triggered by the affected bone.

④ The most common symptom associated with OA is pain, which leads to decreased function and motion. Pain relief is the primary objective of medication therapy.

⑤ Manifestations of OA are local, affecting one or a few joints; the knees are most commonly affected, as well as the hips and hands.

⑥ Nonpharmacologic therapy is the foundation of the treatment plan for all patients with OA. Nonpharmacologic therapy should be initiated before or concurrently with pharmacologic therapy.

⑦ Based upon efficacy, safety, and cost considerations, scheduled acetaminophen, up to 4 g/day, should be tried initially for pain relief in knee and hip OA. If this fails, nonsteroidal anti-inflammatory drugs (NSAIDs; topical or oral) are recommended, if there are no contraindications.

⑧ Topical NSAIDs, in lieu of oral NSAIDs, are recommended for patients older than 75 years of age to decrease the risks of systemic toxicity.

⑨ Strategies to reduce NSAID-induced gastrointestinal (GI) toxicity include the use of nonacetylated salicylates, COX-2 selective inhibitors, or the addition of misoprostol or a proton pump inhibitor.

⑩ Other agents useful in treating knee OA include intra-articular injections of corticosteroids, duloxetine, or tramadol.

BEYOND THE BOOK

BEYOND THE BOOK

This activity is designed to build skills in developing a safe-and-effective patient-specific PLAN as part of the patient care process.

Create a table of drug treatment options for a patient with knee, hip, and hand osteoarthritis and a history of a myocardial infarction.

INTRODUCTION

Osteoarthritis (OA) is the most common joint disease and one of the leading causes of disability in the United States.[1] Knee OA alone is as important a contributor to disability as cardiovascular (CV) disease and more important than other comorbidities. OA is a common co-occurrence with other chronic health conditions that adversely affect quality of life.[1]

The progressive destruction of articular cartilage has long been appreciated in OA, but OA involves the entire diarthrodial joint, including articular cartilage, synovium, capsule, and subchondral bone, with surrounding ligaments and muscles also playing important roles. Changes in structure and function of these tissues produce clinical OA, characterized by joint pain and tenderness, with decreased range of motion, weakness, joint instability, and disability.

This chapter will review the epidemiology, etiology, pathophysiology, and clinical presentation of OA. It then will focus on nonpharmacologic and pharmacologic treatments for OA. Because millions of persons take medications for OA, the overall risks posed by these medications require careful consideration, particularly by clinicians who treat or advise patients on drug therapy for OA. This chapter examines the risks and benefits of OA treatments, with emphasis on those individuals who have the highest risk for adverse events, to help clinicians maximize benefits and minimize risks to their patients with OA.

EPIDEMIOLOGY

① During 2013 to 2015, an estimated 54.4 million adults in the United States reported doctor-diagnosed arthritis (osteoarthritis, rheumatoid arthritis, gout, lupus, or fibromyalgia), with 23.7 million reporting arthritis-attributable activity limitation (AAAL).[1] The prevalence of AAAL among adults with arthritis increased by almost 20% over time (2002-2015).[1] Arthritis is projected to affect 78.4 million adults by 2040.[2] OA imposes a tremendous cost burden with combined arthritis-attributable medical expenditures and earnings losses totaling approximately $303 billion dollars in 2013.[3] The US Medical Expenditure Panel Survey found that arthritis-attributable medical expenditures were $139.8 billion, representing 11% of the total medical expenditures in 2013.[3] Among all adults in the US population, adults with arthritis had the highest overall average cost per person ($9,233), followed by adults with at least one nonarthritis chronic condition ($6,272) and those with no chronic conditions ($1,369).[3] Total hospital costs associated with the specific diagnosis of osteoarthritis were $16.5 billion attributed to 1 million hospital stays in 2013.[4] Arthritis-attributable lost earnings were $163.7 billion with almost half of lost earnings due to lower adjusted per-person earnings for those with arthritis.[3]

Prevalence by Age, Sex, and Race

Prevalence estimates for OA vary depending on the age group of interest, gender, ethnic group, and the specific joint involved. Estimates also depend on the specific means by which OA is assessed and documented. Clinical OA is based on physical exam and patient history, whereas radiographic OA is determined by x-ray or other imaging, and symptomatic OA is based on patient history and physical exam plus x-ray. OA is more prevalent with increasing age. In the United States, the prevalence of self-reported doctor-diagnosed arthritis in the 2013 to 2015 National Health Interview Survey (NHIS) is 22.7% for all persons over age 18, but 49.6% for persons age 65 and older.[1] Prevalence for AAAL among persons with doctor-diagnosed arthritis is 43.5% for all persons over age 18 and 44% for persons age 65 and older.[1] Radiologically confirmed hip OA shows clear trends through all age groups, affecting 1.6% of those between ages 30 and 39, up to a prevalence of 14% in those over 85 years of age.[5] Radiographic hand OA is found in 5% of those aged 40, but in 65% of those older than 80 years of age.[6]

Prevalence of physician-diagnosed arthritis is 26.3% in White populations, and ranges from 11.1% for Asian populations to 21.8% for Black populations.[1] African American men are approximately 35% more likely to have radiographic knee OA and twice as likely to have more severe knee OA than White men.[7] No significant differences were found between the prevalence of knee OA in Black women and White women, but Black women were 50% more likely than White women to have more severe involvement.[7] Among adults with arthritis, the prevalence of severe joint pain is significantly higher in women (29.7%), non-Hispanic Blacks (45.6%), those with less than a high school education (40.2%), and those unable to work (51.9%).[8] Women are also more likely to have inflammatory OA of the proximal and distal interphalangeal joints of the hands, giving rise to the formation of Bouchard and Heberden nodes, respectively (Fig. 110-1).

FIGURE 110-1

Heberden nodes (distal interphalangeal joint) noted on all fingers and Bouchard nodes (proximal interphalangeal joint) noted on most fingers. *(Reproduced, with permission, from Johnson BE. Arthritis: Osteoarthritis, gout, and rheumatoid arthritis. In: South-Paul JE, Matheny SC, Lewis EL, eds. CURRENT Diagnosis and Treatment in Family Medicine. 4th ed. New York, NY: McGraw Hill; 2015.)*

Incidence

As the incidence of a disease describes the number of newly diagnosed cases each year, OA poses a challenging situation for determining disease incidence. These reasons include: (1) not all patients with OA seek medical treatment; (2) OA is common within the population; (3) many effective treatments are available over the counter, promoting self-treatment; (4) not all radiographically diagnosed OA is symptomatic and patients may not be formally diagnosed with OA; and (5) many patients have multiple affected joints, making it difficult to track the overall occurrence of OA in these individuals.

ETIOLOGY

② The etiology of OA is multifactorial and complex, with development of OA depending on interplay between person-level risk factors and joint-level risk factors.[9] Many patients have more than one risk factor for the development of OA. The most common risk factors for the development of OA include age, obesity, sex, occupation, participation in certain sports, history of joint injury or surgery, and genetic predisposition.

Obesity

Obesity is the most important preventable risk factor for OA. This linkage is strongest for knee OA, although hip OA and even hand and wrist OA may be linked with obesity. The etiology of this association of OA in non-weight-bearing joints is thought to be the adverse metabolic and inflammatory effects produced by obesity.[10] As the epidemic of obesity spreads in the United States and in other developed countries, so will the burdens imposed by OA.

For every five unit increase in BMI, the risk of knee OA increases 35%.[9] Obesity often precedes OA and contributes to its development, rather than occurring as a result of inactivity from joint pain. In an 11-year study of approximately 30,000 Norwegian men and women, obesity significantly increased the risk of developing OA.[11] Men who were obese at baseline had a 2.8-fold increase in developing knee OA compared to the nonobese men, whereas women who were obese at baseline had a 4.4-fold increased risk in developing knee OA compared to the nonobese women. Also, there was an increased risk for severe knee OA in obese subjects.[11]

Occupation, Sports, and Trauma

OA risk is increased for people in occupations involving excessive mechanical stress. Work that involves prolonged standing, kneeling, squatting, lifting, or moving of heavy objects increases risk of OA. Such occupations include construction, mining, healthcare assistance, factory work, carpentry, and farming.[9] Repetitive motion also contributes to hand OA, with the dominant hand usually affected. Risk for OA depends on the type and intensity of physical activity and whether injury incurred in the activity. Increased risk of OA is associated with participation in activities such as wrestling, soccer, weight lifting, football, and hockey, although recreational participants do not have the increased risk seen in the professional athlete.[12] Studies that have included running, including long distances, have produced decidedly mixed results.[12] In the study of 30,000 Norwegians, exercise intensity was not associated with any increased risk in the obese subjects compared to those of normal weight.[11]

Traumatic knee injury, either during sports or in accidents, significantly increases the risk of knee OA over a 10-year period.[12] These injuries include anterior cruciate ligament tears, meniscal tears, and direct cartilage injuries.[9] Meniscal damage increases the risk of knee OA because of the loss of proper load bearing and shock absorption, and increased focal load on cartilage and on subchondral bone. Quadriceps muscle weakness is also recognized to increase the risk for knee OA, as these muscles are important in maintaining joint stability.[10] As proper alignment of the joint structures is critical to proper function of the joint, knee malalignment increases risk of developing OA. In the person who already has OA, knee malalignment is strongly associated with faster progression of OA.[10]

Genetic Factors

OA is a complex disease with a strong genetic component. The genetic contribution to OA has been supported by many studies and it is estimated that 30% of the risk of OA is genetically determined.[13] There is not a single genetic variant responsible for OA, but likely thousands of loci associated with the complex nature of the disease. Identification of these genetic loci may promote development of agents to prevent OA or to slow or halt its progression. Heberden nodes are 10 times more prevalent in women than in men, for example, with a twofold higher risk if the woman's mother had them. Genetic links have been shown with OA of the first metatarsophalangeal joint and with generalized OA. Twin studies indicate that OA can be attributed substantially to genetic factors.[14]

One approach OA researchers have used is the candidate gene approach which is hypothesis based and focuses on genes with known function which could be plausibly linked with the OA. This approach requires a priori knowledge of disease etiology and only very small regions of the genome can be studied at a time. Studies of 199 candidate genes found that only two variants (COL11A1 and VEGF genes) reached significance.[13] These results confirm that using existing joint biology knowledge to identify genetic variants is unlikely to facilitate the understanding of the genetic risks of OA.

Genome-wide association studies (GWAS) use a hypothesis-free methodology that involves scanning hundreds of thousands or millions of genetic markers, in the form of single-nucleotide polymorphisms (SNPs). Using GWAS studies, at least 21 independent susceptibility loci to OA have been found.[13] A meta-analysis of GWAS with 6,709 knee OA cases and 44,439 controls revealed that the Chrom7Q22 locus was highly significantly associated with knee OA. The locus also included six genes which code for proteins that are known to be expressed in joint tissues.[15]

It is quite likely that the genetic risk of developing OA, like many other diseases, is determined by a combination of genetic differences. This underscores the point that understanding of the genetics and pathology of OA is in its early stages.

PATHOPHYSIOLOGY

OA falls into two major etiologic classes. *Primary* (*idiopathic*) *OA*, the more common type, has no identifiable cause. *Secondary OA* is that associated with a known cause such as inflammation, trauma, metabolic or endocrine disorders, and congenital factors.[16]

The old view of OA as a "wear-and-tear" or degenerative disease, largely focused on joint cartilage, has long been superseded by an appreciation of the dynamic nature of OA and that it represents a failure of the joint and surrounding tissues.[10] Some changes in the OA joint may reflect compensatory processes to maintain function in the face of ongoing joint destruction. Not only biomechanical forces but also inflammatory, biochemical, and immunologic factors are involved. An appreciation of the biology and function of normal cartilage can aid in understanding osteoarthritic cartilage and is summarized below.

Normal Cartilage

Function, Structure, and Composition of Cartilage

Articular cartilage possesses viscoelastic properties that provide lubrication with motion, shock absorbency during rapid movements, and load support. In synovial joints, articular cartilage is found between the synovial cavity on one side and a narrow layer of calcified tissue overlying subchondral bone on the other side (Fig. 110-2).[16,17] The layer of cartilage is narrow, with human medial femoral articular cartilage being approximately 2 to 3 mm thick. Despite this, healthy articular cartilage in weight-bearing joints withstands millions of cycles of loading and unloading each year. Cartilage is easily compressed, losing up to 40% of its original height when a load is applied. Compression increases the area of contact and disperses force more evenly to underlying bone, tendons, ligaments, and muscles. In addition, cartilage is almost frictionless, and together with its compressibility, this enables smooth movement in the joint, distributes load across joint tissues to prevent damage, and stabilizes the joint.

FIGURE 110-2

Characteristics of osteoarthritis in the diarthrodial joint. (*Reprinted, with permission, from Loeser RF. Age-related changes in the musculoskeletal system and the development of osteoarthritis. Clin Geriatr Med. 2010;26(3):371-386.)*

Strength, a low coefficient of friction, and compressibility of cartilage derive from its unique structure. Cartilage is a complex, hydrophilic, extracellular matrix (ECM). It is approximately 70% water, 10% collagen, 8% proteoglycans, chondrocytes, other proteins, and long hyaluronic acid molecules.[18] The two major structural components in articular cartilage are type II collagen and aggrecans.[16] Type II collagen has a tightly woven triple helical structure, which provides the tensile strength of cartilage. Aggrecan is a proteoglycan linked with hyaluronic acid, providing the long aggrecan molecules a high negative charge. These are squeezed together by surrounding fibrils of type II collagen. The strong electrostatic repulsion of proteoglycans held in close proximity gives cartilage the ability to withstand further compression. Within the cartilage ECM, chondrocytes, the only cells in cartilage, are responsible for laying down all the components of cartilage.

Normal cartilage turnover helps repair and restore cartilage in response to demands of joint loading and during physical activity. In adults, cartilage chondrocyte metabolism is slow and is regulated by growth factors, including bone morphogenetic protein 2, insulin-like growth factor-1, and transforming growth factor, and by catabolism and proteolysis stimulated by matrix metalloproteinases (MMPs), tumor necrosis factor-*α* (TNF-*α*), interleukin-1, and other cytokines. Tissue inhibitors of metalloproteinase (TIMP) also contribute to the balance by restraining the catabolic actions of MMPs. If cartilage is injured, chondrocytes react by removing the damaged areas and increasing synthesis of matrix constituents to repair and restore cartilage.[17]

Other components supporting healthy joints are the joint protective mechanisms, such as muscles bridging the joint, sensory receptors in feedback loops to regulate muscle and tendon function, supporting ligaments, and subchondral bone that has shock-absorbent properties.

Finally, note that adult articular cartilage is avascular, with chondrocytes nourished by synovial fluid. With movement and cyclic loading and unloading of joints, nutrients flow into the cartilage, whereas immobilization reduces nutrient supply. This is one of the reasons that normal physical activity is beneficial for joint health.

Osteoarthritic Cartilage

③ Important contributors to the development of OA are local mechanical influences, genetic factors, inflammation, and aberrant chondrocyte function leading to loss of articular cartilage.[16,19] At a molecular level, OA pathophysiology involves the interplay of dozens, if not hundreds, of extracellular and intracellular molecules with roles including chondrocyte regulation, phenotypic changes, proteolytic degradation of cartilage components, and interactions between articular cartilage, underlying subchondral bone, and the joint synovium.[10,19]

OA most commonly begins with damage to articular cartilage, through trauma or other injury, excess joint loading from obesity or other reasons, or instability or injury of the joint that causes abnormal loading. In response to cartilage damage, chondrocyte activity increases in an attempt to remove and repair the damage. Depending on the degree of damage, the balance between breakdown and resynthesis of cartilage can be lost, and a vicious cycle of increasing breakdown can lead to further cartilage loss and apoptosis of chondrocytes.[10,19] Studies have revealed several aspects of the complex nature of OA.

There is increased appreciation of the role of tissues beyond cartilage, within the joint and surrounding subchondral bone.[19] Subchondral bone undergoes pathologic changes that may precede, coincide with, or follow damage to the articular cartilage. In OA, subchondral bone releases vasoactive peptides and MMPs, and damage to subchondral bone may trigger further damage to articular cartilage.[18] Neovascularization and subsequent increased permeability of the adjacent cartilage contribute further to cartilage loss.

Joint space narrowing results from loss of cartilage, which can lead to a painful, deformed joint (Fig. 110-3). Remaining cartilage softens and develops fibrillations (vertical clefts into the cartilage), followed by splitting off of more cartilage and exposure of underlying bone.[18] During this time, adjacent subchondral bone undergoes further pathologic changes, cartilage is eroded completely, leaving denuded subchondral bone, which becomes dense, smooth, and glistening (eburnation). A more brittle, stiffer bone results, with decreased weight-bearing ability and development of sclerosis and microfractures. New bone formations or osteophytes also appear at joint margins, distant from cartilage destruction and are thought to arise from local and humoral factors. There is direct evidence that osteophytes can help stabilize osteoarthritic joints.[16]

FIGURE 110-3

Plain x-ray films of the knee demonstrating joint space narrowing. *(Reproduced, with permission, from Johnson BE. Arthritis: Osteoarthritis, gout and rheumatoid arthritis. In the joint capsule and synovium, inflammatory changes and pathologic changes can occur.[19] Contributors to inflammation may include crystals or cartilage shards in synovial fluid. Other possible factors are interleukin-1, prostaglandin E_2, TNF-α, and nitric oxide that are found in synovial fluid. With inflammatory changes in the synovium, effusions and synovial thickening occur.

④ The pain of OA is not related to the destruction of cartilage but arises from the activation of nociceptive nerve endings within the joint by mechanical and chemical irritants.[10,16] OA pain may result from distension of the synovial capsule by increased joint fluid, microfracture, periosteal irritation, or damage to ligaments, synovium, or the meniscus. Consequently, x-ray changes in OA correlate poorly with pain severity.

CLINICAL PRESENTATION

Diagnosis

⑤ The diagnosis of OA is made through history, physical examination, characteristic radiographic findings, and laboratory testing.[20] The major diagnostic goals are (1) to discriminate between primary and secondary OA and (2) to clarify the joints involved, severity of joint involvement, and response to prior therapies, providing a basis for a treatment plan. The American College of Rheumatology has published traditional diagnostic criteria and “decision trees” for OA diagnosis.[20] As with all guidelines, the authors stress these are for assisting the clinician rather than replacing clinical judgment. For example, traditional criteria are as follows: (1) For hip OA, a patient must have pain in the hip and at least two of the following three: an erythrocyte sedimentation rate <20 mm/hr (5.6 µm/s), femoral or acetabular osteophytes on radiography, or joint space narrowing on radiography. This provides a sensitivity of 89% and a specificity of 91%. For a clinical diagnosis of knee OA, a patient must have pain at the knee and osteophytes on radiography plus one of the following: age older than 50 years, morning stiffness no more than 30 minutes, crepitus on motion, bony enlargement, bony tenderness, or no palpable warmth. This provides a sensitivity of 95% and a specificity of 69%. The addition of laboratory or radiographic data further improves accuracy of diagnosis. Criteria for hand OA have also been published.[21]

Prognosis

The prognosis for patients with primary OA is variable and depends on the joint involved. If a weight-bearing joint or the spine is involved, considerable morbidity and disability are possible. In the case of secondary OA, the prognosis depends on the underlying cause. Treatment of OA may relieve pain or improve function but does not reverse preexisting damage to the joint.

CLINICAL PRESENTATION: OSTEOARTHRITIS

Age

- Usually occurs in older adults (≥65 years of age)

Gender

- Age <45 years more common in men
- Age >45 years more common in women

Symptoms

- Pain
- Deep, aching character
- Pain on motion
- Stiffness in affected joints
- Resolves with motion, recurs with rest (“gelling phenomenon")
- Usually duration <30 minutes
- Often related to weather
- Limited joint motion
- May result in limitations of activities of daily living
- Instability of weight-bearing joints

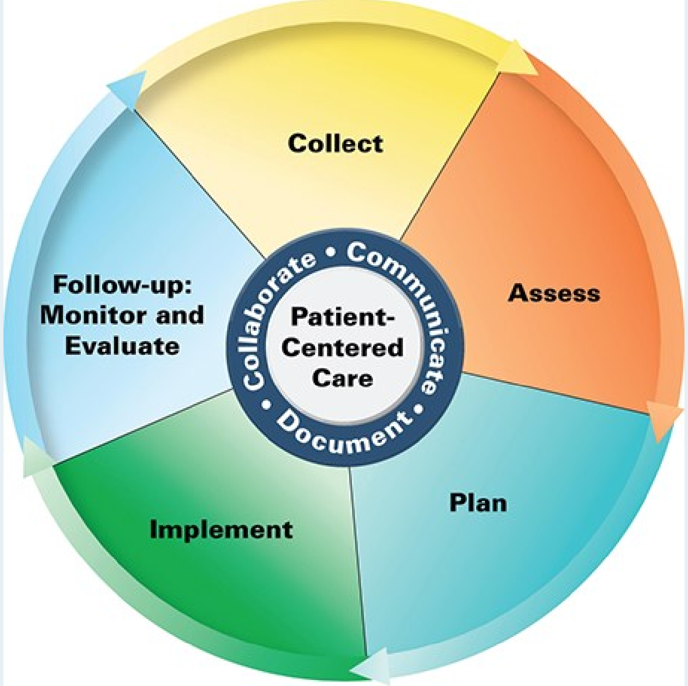
Signs, history, and physical examination

- Monoarticular or oligoarticular, asymmetrical involvement
- Hands
  - Distal interphalangeal joints
    - Herberden nodes (osteophytes or bony enlargements) (Fig. 110-1)
  - Proximal interphalangeal joints
    - Bouchard’s nodes (osteophytes)
  - First metacarpal joint
    - Osteophytes give characteristic square appearance to hands
- Knee
  - Pain related to climbing stairs
  - Transient joint effusion
  - Genu varum (“bow-legged”)
- Hips

  - Groin pain during weight-bearing exercises
  - Stiffness, especially after activity
  - Limited joint movement
- Spine
  - Lumbar involvement is most common at L3 and L4
  - Paresthesia
  - Loss of reflexes
- Feet
  - Typically involves the first metatarsophalangeal joint
- Shoulder, elbow, acromioclavicular, sternoclavicular, temporomandibular joints may also be affected.
- Observation on joint examination
  - Bony proliferation or occasional synovitis
  - Local tenderness
  - Crepitus
  - Limited motion with passive/active movement
  - Deformity
- Radiologic Evaluation
  - Early mild OA
    - Radiographic changes are often absent
  - Progressive OA
    - Joint space narrowing (Fig. 110-3)
    - Subchondral bone sclerosis
    - Marginal osteophytes
- Late OA
  - Abnormal alignment of joints
  - Effusions

PATIENT CARE PROCESS

Patient Care Process for the Management of Osteoarthritis*



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, weight, height, race, sex, pregnant)
- Patient history (past medical, family, social—trauma, diet, exercise, alcohol use)
- Symptom information: type and location of pain, duration, effect of motion and rest, range of motion and limitations on activities, joint instability
- Current and past medications, including nonprescription agents and dietary supplements, and medications' relief of symptoms
- Objective data
  - Physical examination, appearance of joints
  - Radiologic evaluation—changes in joints, subchondral bone sclerosis, effusions
  - Body mass index (presence of overweight or obesity)

Assess

- Distribution and severity of joint involvement
- Impact of symptoms on patients' movements, health-related quality of life, amount of disability

Plan

- Patient education about disease, prognosis, treatment options, application and use of topical products
- Nonpharmacologic therapy (see Table 110-1)—weight loss (if overweight or obese), exercise, surgery (for severe pain or functional disability)
- Drug therapy regimen including specific analgesics, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Figs. 110-4 and 110-5 and Tables 110-2 and 110-3)

- Monitoring parameters including efficacy (eg, symptom relief) and safety (medication-specific adverse effects) (see Table 110-3)
- Self-monitoring of symptoms, exercise, and weight—where and how to record results
- Referrals to other providers when appropriate (eg, physician, orthopedic surgeon, physical therapist, dietician)

Implement[*]

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Assess symptom relief, effectiveness of weight loss and exercise programs
- Presence of adverse effects (see Table 110-3), including CV and renal effects of NSAIDs and hepatic effects of acetaminophen
- Closely monitor proper use of opioids, including dependence, addiction, tolerance, hyperalgesia, and diversion (see text); joint replacement may be preferred to chronic opioids
- Patient adherence to treatment plan using multiple sources of information

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 110-1

Nonpharmacologic Interventions in the Treatment of OA

Intervention	Strength of Recommendation
Exercise	Strong
Weight loss (if overweight)	Strong
Patient education	Strong
Use of assistive device (ie, cane)	Moderate
Use of shoe insoles	Moderate
Application of heat	Moderate
Use of fitted knee braces	Minimal
Lateral patellar taping	Minimal
Passive exercise alone	Minimal

Data from References [22,23].

Robustness of recommendation: Strong—fully supported by evidence-based guidelines; Moderate—supported by evidence-based guidelines; Minimal—little support by evidence-based guidelines.

TABLE 110-2

Dosing of Medications for Osteoarthritis

Drug	Brand Name	Starting Dose	Usual Range	Special Population Dose	Other
Oral analgesics					
Acetaminophen	Tylenol	325-500 mg three times a day	325-650 mg every 4-6 hours or 1 g three to four times/day	Chronic alcohol intake, hepatic disease	Contained in many combination analgesics
Tramadol Tramadol ER	Ultram Ultram ER	25 mg in the morning 100 mg daily	Titrate dose in 25-mg increments to reach a maintenance dose of 50-100 mg three times a day. Titrate to 200-300 mg daily	Creatinine clearance <30 mL/min (0.5 mL/s)—maximum dose is 200 mg daily Do not use if creatinine	May need to taper dose upon discontinuation to prevent withdrawal symptoms

				clearance <30 mL/min (0.5 mL/s)	
Hydrocodone/acetaminophen	Lortab, Vicodin, Norco	5 mg/325 mg three times daily	2.5-10 mg/325-650 mg three to five times daily	Titrate dose slowly in older adults (age >65 years)	Maximum dose limited by total daily dose of acetaminophen
Oxycodone/acetaminophen	Percocet	5 mg/325mg three times daily	2.5-10 mg/325-650 mg three to five times daily	Titrate dose slowly in older adults (age >65 years)	Maximum dose limited by total daily dose of acetaminophen
Topical analgesics					
Capsaicin 0.025% or 0.15%	Capzasin-HP		Apply to affected joint three to four times per day		—
Diclofenac 1% gel	Voltaren		Apply 2 or 4 g per site as prescribed, four times daily		
Diclofenac 1.3% patch	Flector		Apply one patch twice daily to the site to be treated, as directed		
Diclofenac 2% solution	Pennsaid		Apply 40 mg (two pump actuations) twice daily		
Intra-articular Corticosteroids					
Triamcinolone	Kenalog	5-15 mg/joint	10-40 mg/large-joint (knee, hip, shoulder)	If multiple joints injected, maximum total dose is usually 80 mg	Often administered concomitantly with a local anesthetic
Methylprednisolone acetate	Depo-Medrol	10-20 mg/joint	20-80 mg/large-joint (knee, hip, shoulder)	10-40 mg for medium joints (elbows, wrists)	

Nonsteroidal anti-inflammatory drugs (NSAIDs)					
Aspirin, plain, buffered, or enteric-coated	Bayer, Ecotrin, Bufferin	325 mg three times a day	325-650 mg four times a day		Doses of 3,600 mg/day are needed for anti-inflammatory activity
Celecoxib	Celebrex	100 mg daily	100 mg twice daily or 200mg daily		
Diclofenac XR Diclofenac IR	Voltaren-XR Cataflam	100 mg daily 50 mg twice a day	100-200 mg daily 50-75 mg twice a day		
Diflunisal	Dolobid	250 mg twice a day	500-750 mg twice a day		
Etodolac	Lodine	300 mg twice a day	400-500 mg twice a day		
Fenoprofen	Nalfon	400 mg three times a day	400-600 mg three to four times a day		
Flurbiprofen	Ansaid	100 mg twice a day	200-300 mg/day two to four divided doses		
Ibuprofen	Motrin, Advil	200 mg three times a day	1,200-3,200 mg/day in three to four divided doses		Available OTC and Rx
Indomethacin Indomethacin SR	Indocin Indocin SR	25 mg twice a day 75 mg SR once daily	Titrate dose by 25-50 mg/day until pain controlled or maximum dose of 50 mg three times a day Can titrate to 75 mg		

			SR twice daily if needed		
Ketoprofen	Orudis	50 mg three times a day	50-75 mg three to four times a day		
Meclofenamate	Meclomen	50 mg three times a day	50-100 mg three to four times a day		
Mefenamic acid	Ponstel	250 mg three times a day	250 mg four times a day		FDA approval for 1 week of therapy
Meloxicam	Mobic	7.5 mg daily	15 mg daily		
Nabumetone	Relafen	500 mg daily	500-1000 mg one to two times a day		
Naproxen	Naprosyn	250 mg twice a day	500 mg twice a day		
Naproxen sodium Naproxen sodium DR	Anaprox, Aleve Naprelan	220 mg twice a day	220–550 mg twice a day 375-750 mg twice a day		Available OTC and Rx
Oxaprozin	Daypro	600 mg daily	600-1200 mg daily		
Piroxicam	Feldene	10 mg daily	20 mg daily		
Salsalate	Disalcid	500 mg twice a day	500-1000 mg two to three times a day		

TABLE 110-3

Monitoring of Medications Used in Osteoarthritis Treatment

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Oral analgesics			
Acetaminophen	Hepatotoxicity	Total daily dose limits	Use caution with multiple acetaminophen-containing products—total 4 g limit (or less in patients with hepatic dysfunction)
Tramadol	Nausea, vomiting, somnolence	No routine labs recommended	Drug-drug interaction with other serotonergic medications
Opioids	Sedation, constipation, nausea, dry mouth, hormonal changes	No routine labs recommended	Risks of addiction, dependence, and drug diversion
NSAIDs	Dyspepsia, CV events, GI bleeding, renal impairment	BUN/Creatinine, Hgb/Hct, blood pressure	Risks higher in those older than 75 years of age
Topical analgesics			
Capsaicin	Skin irritation and burning	Inspection of areas of application	Wash hands thoroughly after application
NSAIDs	Skin itching, rash, irritated dyspepsia, CV events, GI bleeding, renal impairment	Inspection of areas of application. As needed: BUN/Creatinine, Hgb/Hct, blood pressure	Wash hands thoroughly after application. Avoid oral NSAID or aspirin other than cardioprotective dose. Ensure patient applies gel, solution, or patch correctly
Injectable drugs			
Intra-articular corticosteroids	Hypertension, hyperglycemia	Glucose, blood pressure	HPA axis suppression if used too frequently
Intra-articular hyaluronates	Local joint swelling, stiffness, pain	No routine labs recommended	Less effective than intra-articular corticosteroids; expensive

TREATMENT

Desired Outcome

Management of the patient with OA begins with a diagnosis based on a careful history, physical examination, radiographic findings, and an assessment of the extent of joint involvement. Treatment should be tailored to each individual. Goals are (1) to educate the patient, family members, and caregivers; (2) to relieve pain and stiffness; (3) to maintain or improve joint mobility; (4) to limit functional impairment; and (5) to maintain or improve quality of life.[24,25] About half of the US population has one chronic health condition, with 25% having two or more conditions.[26] With nearly 25% of the US adults with at least one chronic health condition having arthritis, it is essential that comprehensive patient-centered medication management is provided to these patients to maximize treatment goals for OA and other chronic conditions, while minimizing medication-related adverse outcomes.

General Approach to Treatment

Treatment for each OA patient depends on the distribution and severity of joint involvement, comorbid disease states, concomitant medications, and allergies. Management for all individuals with OA should begin with both oral and written patient education, a customized activity and exercise program, and weight loss, if the patient is overweight or obese.[24,25] A multidisciplinary intervention for knee OA initiated by pharmacists has been shown to improve adherence to OA guideline recommendations, decrease pain scores, and improve functional assessment scores.[27] These types of multidisciplinary disease state management programs that implement strategies to provide comprehensive care should be offered to all OA patients to maximize outcomes.

The primary objective of medication is to alleviate pain.[24,25] Scheduled acetaminophen, up to 4 g/day, should be tried initially (knee, hip), if contraindications are not present. Application of topical NSAIDs over specific joints (knee, hands) and topical capsaicin (hands) are recommended as initial therapy. Nonsteroidal anti-inflammatory drugs (NSAIDs) or possibly a cyclooxygenase-2 (COX-2)–selective inhibitor (celecoxib) can be prescribed after careful risk assessment if additional pain control is needed. Intra-articular corticosteroid injections (knee or hip) can relieve pain and are offered concomitantly with oral analgesics or after failed trials of first-line medications, depending on the practitioner's preference. With centrally acting serotonin reuptake inhibition and analgesic properties, tramadol can also be considered if acetaminophen or topical treatment is ineffective or not tolerated.

Consideration may also be given to duloxetine or, rarely, hyaluronic acid injections when additional pain control is needed for knee OA. When symptoms are persistent or there is significant loss of function, joint replacement can be appropriate if the patient is a surgical candidate.

There is general agreement that glucosamine and/or chondroitin and topical medications lack uniform efficacy in the treatment of hip and knee OA pain and are not preferred treatment options.

Nonpharmacologic Therapy

⑥ Nonpharmacologic therapy is an integral part of the treatment plan for all patients with OA.[24,25,28] Nonpharmacologic therapy is the only available treatment that has been shown to delay the progression of OA.[2,29] Delaying the progression of OA through active participation in nonpharmacologic therapy is critical to prevent future functional impairment. Patient-specific characteristics such as (1) number and location of affected joints, (2) degree of functional impairment, (3) body mass index, (4) motivation, and (5) overall health status determine which nonpharmacologic therapies should be offered. Nonpharmacologic therapy should be ongoing treatment for all patients, even those who require pharmacologic therapy for pain control (Table 110-1).[2,28,29]

Patient Education

The first step in OA treatment is patient education about the disease process, the extent of OA, the prognosis, and treatment options. Education is paramount, in that OA is often seen as a wear-and-tear disease, an inevitable consequence of aging for which nothing helps. Even worse, patients may resort to the use of alternative but unproven medications or treatments. Organizations such as the Arthritis Foundation provide a wealth of educational information for patients regarding OA, OA medications, and local clinics and agencies offering physical and economic assistance. Exercise, weight loss, and nutritional information are also available. Most educational information is readily available online for patient use. Several mobile applications are available to provide education, track symptoms and exercise, and encourage better self-management of OA.

The benefits of patient education have been documented in a variety of programs.[22,28] These programs are provided across a wide spectrum of delivery methods: from trained volunteers using telephone calls to group sessions for patient support to one-on-one educational sessions with physical therapists or nurse educators. While nearly all of these delivery methods are effective, cost of delivery is highly variable. Long-term cost-effectiveness is important for sustainability of these patient education programs.

Weight Loss

The association between OA and obesity has been well established. Studies also indicate a strong association between increasing BMI and surgical replacement of the hip and knee joints.[30] Weight loss of amounts as small as 4% body weight can lessen OA pain in the knee.[31] Greater amounts of weight loss, especially when associated with regular exercise improve joint function and substantially lessen pain.[2,29] Modest weight loss (5%) has been shown to provide some relief in obese patients with OA but the goal should be an initial decrease in body weight of at least 10% to provide significant reductions in pain.[30] The Intensive Diet and Exercise for Arthritis trial (IDEA) found that after 18 months, overweight and obese adults with knee OA who participated in the diet and exercise treatment group had less inflammation, less pain, better function, and better quality of life.[32] Weight loss requires a motivated patient, but all patients with OA who also have obesity and overweight should be encouraged and supported in their efforts to optimize their body size . Effective behavior change strategies should be employed to promote weight loss in patients with OA.[29]

Exercise

Exercise programs can improve joint function and can decrease disability, pain, and analgesic use by OA patients.[2,33] Low-impact aerobic exercise including both land- and water-based methods are preferred.[34] Exercises can be taught and then observed before the patient exercises at home. The frequency, types of exercise, and setting of exercise are still uncertain, but patients who exercise have decreased pain and increased physical function.[35] The patient should be instructed to decrease the number of repetitions if severe pain develops with exercise.

Some regular exercise should be encouraged for all patients with OA.[25] With weak or deconditioned muscles, the load is transmitted excessively to the joints; weight-bearing activities can exacerbate symptoms. Many patients fear that exercise will promote further joint damage and avoid exercise as a means to protect the joint. However, avoidance of regular exercise by those with hip or knee OA leads to further deconditioning and/or weight gain. Further weight gain and deconditioning leads to more pain and impaired joint function, promoting a downward spiral of disability. Exercise therapy in addition to patient education has been shown to decrease or postpone the need for hip replacement surgery in patients with hip OA.[36]

Referral to the physical and/or occupational therapist is especially helpful for developing a customized exercise plan for patients with functional disabilities. The therapist can assess muscle strength and joint stability and recommend exercises and assistive and orthotic devices, such as canes, walkers, braces, heel cups, splints, or insoles for use during exercise or daily activities. Heat or cold treatments help to maintain and restore joint range of motion and to reduce pain and muscle spasms. Warm baths or warm water soaks may decrease pain and stiffness. Heating pads should be used with caution, especially in the elderly. Patients should be warned not to fall asleep on the heat source or to lie on it for more than brief periods to avoid burns.

Surgery

Surgery can be recommended for OA patients with functional disability and/or severe pain unresponsive to medical therapy.[37] Total joint replacement surgeries are quite common and expected to increase. Over 1 million total hip and knee replacement procedures are performed each year in the United States. Seven million individuals are living with an artificial knee or hip, including 620,000 people who have both.[23] Although total knee arthroplasty can decrease pain and improve function for many patients, about 20% experience little or no improvement in pain, disability, and/or quality of life.[38] Patients who are obese are less likely to have improvement in symptoms from knee arthroplasty. Patients also experience less pain and decreased length of hospitalization after surgery if they participate in a supervised exercise program for the first two months that begins on the day of surgery.[39]

Total joint arthroplasty is responsible for a large portion of the direct medical costs associated with OA in the United States. The cost-effectiveness of total knee arthroplasty has been evaluated for a Medicare-age population.[40] Calculations were based on Medicare claims data and costs and outcomes data. Cost projections were calculated for lifetime costs as well as quality-adjusted life expectancy (QALE) for different risk populations and across low-volume to high-volume hospitals. Although total knee arthroplasty was found to be cost-effective across hospital settings and patient risk categories, the procedure was found to be most cost-effective when performed in high-volume centers. The cost-effectiveness of knee arthroplasty was evaluated against nonsurgical management. Knee arthroplasty was cost-effective at both low and high levels of improvement in pain and function in patients with severe knee OA.[41] Direct medical costs associated with joint replacement will continue to increase at a rate higher than predicted rates due to increasing willingness of patients to undergo joint replacement surgery.[3]

Pharmacologic Therapy

Drug therapy in OA is targeted at relief of pain. OA is commonly seen in older individuals who have other medical conditions, and OA treatment is often long term. As such, a conservative and patient-centered approach to drug treatment is warranted (see Figs. 110-4 and 110-5).[24,25,28] Even when pharmacologic therapy is initiated, appropriate nondrug therapies should be continued and reinforced. Specific drug therapy recommendations depend on which joint(s) are affected, response to previous trials of medication, and patient comorbidities.

Knee and Hip OA

First-Line Treatments

Acetaminophen

⑦ The American College of Rheumatology, as well as others, recommend acetaminophen as a first-line treatment for knee and hip OA.[24,25,42] Acetaminophen has been extensively studied in the treatment of knee and hip OA and is more effective than placebo in controlling OA pain.[43] Compared with oral NSAIDs, acetaminophen may be modestly less effective, but have lower risk of serious GI and CV adverse events and as a consequence is preferred to oral NSAIDs as first-line treatment.[28,42]

Oral NSAIDs

The American College of Rheumatology and other key groups recommend nonspecific or COX-2 selective NSAIDs, depending on patient risk factors, as a first-line option for knee and hip OA if the patient fails acetaminophen.[25,26,41] Nonselective and COX-2 selective NSAIDs pose higher risks for GI, renal, and CV adverse events compared to acetaminophen. COX-2 inhibitors carry less risk for both minor and serious GI adverse events in comparison to nonselective NSAIDs (with the exception of diclofenac).[42]

Topical NSAIDs—Knee Only

⑧ The American College of Rheumatology and other authorities recommend topical NSAIDs as a first-line option for knee OA if the patient fails acetaminophen and is preferred to oral NSAIDs for those older than age 75 years.[24,25,42] Topical NSAIDs provide pain relief for OA similar to that obtained with oral NSAIDs but with fewer GI adverse events. Topical NSAIDs offer a favorable safety profile and aren't associated with systemic adverse effects. The most common adverse effect of topical NSAIDs is a localized skin reaction.[44]

Intra-articular Corticosteroids

Intra-articular corticosteroid injections are recommended as alternative first-line treatment for both knee and hip OA when pain control with acetaminophen or NSAIDs is suboptimal.[24,25] Injections can also be administered with concomitant oral analgesic therapy as needed for additional pain control. Intra-articular corticosteroids are generally safe and well tolerated, but should not be administered more frequently than once every 3 months due to risks of systemic adverse effects.

Tramadol

Tramadol is recommended as an alternative first-line treatment of knee and hip pain due to OA in patients who have failed treatment with scheduled full-dose acetaminophen and topical NSAIDs, who are not appropriate candidates for oral NSAIDs, and who are not able to receive intra-articular corticosteroids.[25] Tramadol can also be safely added to partially effective acetaminophen or oral NSAID therapy. Less data are available to support the use of tramadol as monotherapy for OA pain.

Second-Line Treatments

Opioid Analgesics

The American College of Rheumatology recommends opioid analgesics as the primary second-line medication for both knee and hip OA.[25] Opioids may be considered in patients who have not had an adequate response to both nonpharmacologic and first-line pharmacologic therapies. Patients who are at high surgical risk, precluding joint arthroplasty, are also candidates for opioid therapy. When compared to nonopioid medications in a 12-month randomized trial, opioids were not found to be superior in improving pain-related function.[45] Adverse effects, including serious events, limit the routine use of opioids in the treatment of OA pain.

Duloxetine—Knee Only

Duloxetine can be used as adjunctive treatment in patients with knee OA who have had a partial response to first-line analgesics.[24,25] It may be a preferred second-line medication in patients with both neuropathic and musculoskeletal OA pain. Duloxetine has demonstrated efficacy primarily as add-on therapy when there has been less than optimal response to acetaminophen or oral NSAIDs.[46,47] Reduction in pain occurs at about 4 weeks after initiation.[48] Adverse events associated with duloxetine in the treatment of knee OA are most commonly GI, with nausea, vomiting, and constipation being the most common. The recommended dose is 60 mg once daily. However, some patients may benefit from higher doses, up to a maximum dose of 120 mg daily.[48] Adverse events have not been reported in OA trials that most commonly used doses of 60 mg/day. A higher dose is associated with an increased risk of adverse reactions.

Intra-articular Hyaluronic Acid
The American College of Rheumatology, NICE, and others do not routinely recommend the use of intra-articular hyaluronic acid injections for knee OA pain.[24,25,28] HA injections do not provide clinically meaningful improvement in pain and/or function scores, although some studies may report statistical differences in scores. These agents may be associated with serious adverse events such as increased pain, joint swelling, and stiffness. Limited efficacy and risks of serious events limit the routine use of these agents.

Hand OA

First-Line Treatments

NSAIDs
The American College of Rheumatology and NICE recommend topical NSAIDs as a first-line option for hand OA.[28] Application of diclofenac gel compared to placebo topical product for hand OA provided significant relief.[21] No difference was found between the efficacy of oral and topical NSAIDs. Local adverse effects were seen more with topical versus oral NSAIDs but GI adverse effects were more common with oral NSAIDs.[49,50] Efficacy with topical NSAIDs was reported quickly, within 1 to 2 weeks.[21]

Oral NSAIDs are recommended as an alternative first-line treatment for hand OA by the American College of Rheumatology and as second-line therapy in the NICE guidelines.[25,28] For the person who cannot tolerate local skin reactions or who received inadequate relief from topical NSAIDs, oral NSAIDs can offer relief, but the patient then faces increased risk for GI, renal, and CV adverse events.

Topical Capsaicin
Capsaicin cream is recommended as an alternative first-line treatment for hand OA.[25] Clinical trial data supporting the use of capsaicin for the treatment of hand OA is limited to small studies, but demonstrates about 50% reduction in pain scores.[21] Adverse effects associated with capsaicin are primarily skin irritation and burning; therefore, it is a reasonable therapeutic alternative for patients who are not able to take oral NSAIDs.

Tramadol
Tramadol is recommended by the American College of Rheumatology as an alternative first-line treatment for OA of the hand.[25] No studies in hand OA with tramadol have been performed.[21] In clinical practice, tramadol is a therapeutic option for patients who do not respond to topical therapy and are not candidates for oral NSAID treatment due to high GI, CV, or renal risks. Tramadol may also be used in combination with partially effective acetaminophen, topical therapy, or oral NSAIDs.

Drug Class Information

Highlights of drug information is presented here. This section is not intended to be all inclusive but aims to provide pertinent drug information to facilitate the safe-and-effective use of these medications in patients with OA.

First-Line Treatments

Acetaminophen

Pharmacology and Mechanism of Action
Acetaminophen is understood to act within the central nervous system (CNS) by inhibiting synthesis of prostaglandins, agents that enhance pain sensations. Acetaminophen prevents prostaglandin synthesis by blocking the action of central cyclooxygenase (COX). Acetaminophen is well absorbed after oral administration, with bioavailability of 60% to 98%. It achieves peak concentrations within 1 to 2 hours. It is inactivated in the liver by

conjugation with sulfate or glucuronide, and its metabolites are renally excreted.

Adverse Effects

Although acetaminophen is one of the safest analgesics for younger individuals without comorbidities, it carries greater risk in frail older adults.[51] Serious hepatotoxicity, including fatalities, have been well documented with acetaminophen overdose (see Chapter e8, “Clinical Toxicology,” for treatment of acetaminophen overdose).[52] Unintentional overdoses of acetaminophen are due to a variety of circumstances including narrow therapeutic window at the maximum dose (4 g/day), interpatient differences in sensitivity to liver injury from acetaminophen, a wide array of nonprescription and prescription products that contain acetaminophen, which may be hard for patients to identify on the label, and consumers’ lack of knowledge about the association of acetaminophen and serious liver injury.

Acetaminophen-related hepatotoxicity is dose-dependent. Even at therapeutic doses, acetaminophen may cause transient liver enzyme elevations and potentially hepatotoxicity.[53,54] The most common risk factor for liver failure in patients who take acetaminophen is chronic alcohol intake.[55] The FDA has recommended that chronic alcohol users (three or more drinks daily) avoid acetaminophen intake as it increases the risk of liver damage or GI bleeding. Other individuals are not at increased risk of GI bleeding.

Drug-Drug Interactions and Drug-Food Interactions

Drug interactions with acetaminophen can occur; for example, isoniazid can increase the risk of hepatotoxicity. Chronic ingestion of maximal doses of acetaminophen may intensify the anticoagulant effect for patients taking warfarin; such individuals may need closer monitoring. Although food decreases the maximum serum concentration of acetaminophen by approximately half, the overall efficacy is unchanged.

Dosing and Administration

When used for chronic OA, acetaminophen should be administered in a scheduled manner. It may be taken with or without food. Acetaminophen can be taken at 325 to 650 mg every 4 to 6 hours, but the total dose must not exceed 4 g daily (see “Adverse Effects” section above). FDA labeling requirements warn patients about potential liver toxicity if they inadvertently ingest more than the recommended dose when using multiple products containing acetaminophen. Additionally, prescription analgesics containing acetaminophen are limited to 325 mg/tablet to further decrease the opportunity for inadvertent overdose. Acetaminophen should be avoided in the setting of chronic alcohol intake or in those with underlying liver disease.

Oral Nonsteroidal Anti-inflammatory Drugs

Pharmacology and Mechanism of Action

NSAIDs reduce pain, inflammation, and fever by preventing synthesis of tissue prostaglandins and related prostanoids, which play a role in triggering these symptoms. All NSAIDs bind (reversibly) to the cyclooxygenase 2 (COX-2) enzyme, blocking its action and thus prostanoid production. Blockade of prostaglandin synthesis by inhibiting COX enzymes (mainly COX-2) is thought to account for NSAIDs ability to relieve pain and inflammation (Fig. 110-6).[56] Nonselective NSAIDs were developed prior to extensive knowledge of COX enzymes, but in fact they block both COX-2 and COX-1. COX-1 has required “housekeeping” functions such as gastroprotection. COX-2 inhibitors selectively block COX-2 but not COX-1 activity.

FIGURE 110-6

Pathway of synthesis for prostaglandins and leukotrienes. COX-1 and COX-2 are cyclooxygenase-1 and cyclooxygenase-2 enzymes, respectively. The minus (–) sign indicates inhibitory influence. Prostaglandins include PGE_2 and PGI_2; the latter is also known as prostacyclin.

The various NSAIDs exhibit several pharmacokinetic similarities, including high oral availability, high protein binding, and absorption as active drugs (except for sulindac and nabumetone, which require hepatic conversion for activity). There is a broad range of serum half-lives for different NSAIDs, which influence dosing frequency, and potentially, compliance with therapy.[57] Elimination of NSAIDs largely depends on hepatic inactivation, with a small fraction of active drug being renally excreted. NSAIDs penetrate joint fluid, reaching approximately 60% of blood levels.

Adverse Effects Gastrointestinal Effects of Nonselective NSAIDs

The most common adverse effects of NSAIDs involve the GI tract. NSAIDs can cause minor symptoms such as nausea and dyspepsia as well as more serious effects such as ulcers and bleeding.[58–60] All NSAIDs increase ulcer risk, but the serious GI complications associated with NSAIDs include perforations, gastric outlet obstruction, and bleeding. These important GI complications occur in 1.5% to 4% of patients per year. NSAIDs are so widely used that these small percentages translate into substantial morbidity and mortality. Moreover, the risk increases substantially for patients with risk factors including a longer duration of NSAID usage, higher dosage, age older than 60 years, past history of peptic ulcer disease of any cause, history of alcohol use, concomitant use of glucocorticoids, and/or anticoagulants.[56] A patient treated with NSAIDs has a three to five times higher risk of developing GI complications than a patient not treated with these medications.[61]

⑨ Options are available to reduce the GI risk of traditional NSAIDs. (1) Take the lowest dose possible and take only when needed. (2) Take the prostaglandin analog, misoprostol four times daily that reduces the rate of ulcers and serious GI complications. Many patients cannot tolerate the GI adverse events of misoprostol, especially diarrhea. (3) Take a proton pump inhibitor (PPI) or a full-dose H2 blocker daily. The PPI and the H2 blocker do reduce minor GI complaints and reduce the risk of ulcers but are not rigorously proven to decrease the serious complications, possibly because of lack of power to detect rare events.[61]

Another choice that is available to reduce risk of GI events with an NSAID is to take a COX-2 selective inhibitor ("coxib").[58,60] Celecoxib is the only coxib available in the United States. Because this drug does not block the "housekeeping" gene, it may not have the same GI risks, but it is not without GI risk.[55] A meta-analysis showed that COX-2 selective inhibitors were associated with significantly fewer gastroduodenal ulcers and clinically important ulcer complications. Celecoxib has been shown to be as safe to the upper GI tract as a nonselective NSAID plus a PPI.[62] Another concern is the risk associated with NSAID use in patients taking aspirin for cardioprotection. The GI risk is lower in patients taking a coxib medication and low-dose aspirin than a nonselective NSAID. However, in patients with high GI risk the combination may still be harmful and gastroprotection is appropriate.[62]

Dosing and Administration

Administration of NSAIDs must be tailored to the individual patient with OA. Selection of an NSAID depends on the prescriber's experience, medication cost, patient preference, allergies, toxicities, and adherence issues. Individual patient response differs among NSAIDs, so if an inadequate response is obtained with one NSAID, another NSAID may yet provide benefit.[25,28]

Cardiovascular Risk of COX-2 Inhibitors and Traditional NSAIDs

Both nonselective and selective NSAIDs are associated with an increased risk for hypertension, stroke, myocardial infarction (MI), and death. NSAIDs should be avoided in patients with known active ischemic heart disease, cerebrovascular disease, and moderate-to severe heart failure.[56] The mechanism for the CV effects of NSAIDs is not entirely clear.[61] NSAIDs are associated with hypertension, increased preload, volume expansion, and reduced sodium excretion.[63] A large meta-analysis showed some differences among NSAIDs in terms of vascular risk. The risks of diclofenac and ibuprofen were similar to that of coxibs but naproxen was not associated with an increased risk of major vascular events. Overall, coxibs were found to increase vascular risk by approximately one-third.[64] Several randomized controlled trials have compared NSAIDs to evaluate CV safety and found celecoxib to be noninferior to other NSAIDs in terms of CV events. However the celecoxib dose in these trials was lower than the doses previously reported to be associated with increased CV risk. In these trials, more patients also discontinued celecoxib due to lack of efficacy compared to other NSAIDs.[64,65]

In February 2014, an advisory committee to the FDA met to discuss the data relating the CV risk and NSAIDs. After their review it was decided to strengthen the warning label for nonaspirin NSAIDs, warning patients on the risk of heart attack and stroke. The updated labeling warns that CV events can happen at any point during NSAID therapy and the risk may increase with longer treatment and higher doses. The FDA concluded that there was insufficient evidence that the risk of any NSAID was higher or lower than another. An increased risk for CV events is present even in patients with no underlying CV disease. The data reviewed also showed patients taking an NSAID following a first MI were more likely to die in the first year following the MI.[66] Strategies to reduce CV risk with NSAIDs are not well documented. Naproxen may present less CV risk than coxibs and diclofenac at higher doses and therefore seems prudent to consider this when choosing a specific NSAID.[61,62,66]

Other Toxicities Associated with NSAIDs

NSAIDs may cause kidney diseases, including acute renal insufficiency, sodium retention, acute interstitial nephritis, renal papillary necrosis, and accelerated chronic kidney disease. In a trial evaluating NSAID safety, serious renal events occurred at a significantly lower rate in the celecoxib group compared to the ibuprofen group but when celecoxib was compared to naproxen the difference in renal events was not significant.[67] Sodium retention has been reported to occur in up to 25% of NSAID-treated patients. This effect may be clinically important to cause exacerbations of congestive heart failure.[63] Clinical features of these NSAID-induced renal syndromes include increased serum creatinine and blood urea nitrogen, hyperkalemia, elevated blood pressure, peripheral edema, and weight gain. Patients at high risk are those with conditions associated with decreased renal blood flow or taking certain medications. Examples are those with chronic renal insufficiency, congestive heart failure, severe hepatic disease, and nephrotic syndrome, those of advanced age, or those taking diuretics, angiotensin-converting enzyme inhibitors, cyclosporine, or aminoglycosides (Fig. 110-7).

Close monitoring is advisable for high-risk patients taking an NSAID, with monitoring of serum creatinine at baseline and within 3 to 7 days of drug initiation. For those with impaired renal function, the National Kidney Foundation recommends acetaminophen over NSAIDs, although acetaminophen may pose risks, as discussed above.

Coxibs and NSAIDs uncommonly cause drug-induced hepatitis; the two NSAIDs most frequently implicated are diclofenac and sulindac. Patient monitoring should include periodic liver enzymes (aspartate aminotransferase and alanine aminotransferase), with cessation of therapy if these values exceed two to three times the upper limit of normal. Hepatotoxicity associated with NSAIDs is responsible for about 10% of medication-induced liver injury.[68]

Other toxic effects of NSAIDs include hypersensitivity reactions, rash, and CNS complaints of drowsiness, dizziness, headaches, depression, confusion, and tinnitus.[57] NSAIDs should be avoided for patients with asthma who are aspirin-intolerant.

All nonspecific NSAIDs inhibit COX-1–dependent thromboxane production in platelets and thus increase bleeding risk. Unlike aspirin, celecoxib and nonspecific NSAIDs inhibit thromboxane formation reversibly, with normalization of platelet function 1 to 3 days after the drug is stopped. Warfarin and celecoxib are metabolized by the cytochrome P450 isoenzyme CYP2C9; thus, patients receiving warfarin and COX-2 inhibitors should be followed closely.

Finally, if misoprostol is taken for GI protection, great care is indicated. Because of its abortifacient properties, misoprostol is contraindicated in pregnancy and in women of childbearing age who are not maintaining adequate contraception. It must be dispensed in its original container, which carries a warning for these individuals. Misoprostol is also available in a combination product with diclofenac, which bears the same restrictions as misoprostol alone.

Drug-Drug Interactions

Avoidance of concomitant use, or anticipation and careful monitoring, can often prevent serious events when potentially interacting drugs are being considered. The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, other agents that increase bleeding risk, oral hypoglycemics, methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β-blockers, and diuretics.[57] In addition, there are probable drug interactions with tacrolimus for ibuprofen, naproxen, diclofenac, and possibly other NSAIDs.

Specific drug interactions are also seen with celecoxib.[69] Celecoxib metabolism is primarily via CYP2C9.[69] Cytochrome P450 inducers such as rifampin, carbamazepine, and phenytoin have the potential to reduce celecoxib levels. Concomitant administration of celecoxib with fluconazole can increase plasma concentrations of celecoxib, due to fluconazole inhibition of the CYP2C9 isoenzyme. Because warfarin and celecoxib are both metabolized by CYP2C9, patients receiving warfarin and COX-2 inhibitors should be followed closely. Because celecoxib inhibits CYP2D6, it has the potential to increase concentrations of a variety of agents, including antidepressants. Celecoxib is a sulfonamide and is thus noted to be contraindicated for those with sulfa allergies.[69]

Another drug interaction has been noted for those taking some NSAIDs and cardioprotective doses of aspirin. Ibuprofen, used at doses of 400 mg or more, may block aspirin's antiplatelet effect if it is taken prior to aspirin. Patients taking ibuprofen have been advised to take a single dose of ibuprofen at least 30 minutes after taking aspirin, or to take their aspirin at least 8 hours after taking ibuprofen. It is possible that other nonselective NSAIDs, such as naproxen, also may cause such interactions. The ACR recommends that patients taking aspirin who need an oral NSAID for OA choose an NSAID other than ibuprofen or COX-2 selective inhibitors.[25] Acetaminophen does not interfere with the antiplatelet effect of aspirin.

Topical NSAIDs Pharmacology and Mechanism of Action

The mechanism of action of topical NSAIDs is considered to be through inhibition of the COX-2 enzyme in tissues near the site of application. Studies show significant placebo effects which could result from rubbing the product into the skin, which may have a counterirritant effect. Topical NSAIDs are significantly more efficacious compared to placebo vehicle in reducing pain due to musculoskeletal conditions, including osteoarthritis. Most trials have shown topical diclofenac to be as effective as oral NSAIDs, including both oral diclofenac and other comparators.[42,50,70] Diclofenac 1% gel as well as the newer diclofenac solution and diclofenac patches are approved in the United States for osteoarthritis.

Adverse Effects

Compared to oral NSAIDs, topical NSAIDs are associated with many fewer GI adverse events and fewer adverse events overall, except for local application site reactions. In comparison to placebo or oral NSAIDs, topical NSAID use is associated with more local adverse events, most often mild skin reactions such as itching or rash, but with few serious adverse effects. Meta-analyses and reviews have found similar tolerability between topical NSAIDs and placebo. Topical NSAIDs have not shown a significant link between their use and increased risk of CV events.[44] From 1% to 15% of topical NSAIDs enter the systemic circulation, but usually less than 5% contribute to its greater safety profile.[70,71]

Drug-Drug Interactions

Interactions listed for topical diclofenac are the same as those listed above for oral NSAIDs. The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, and other agents that increase bleeding risk, oral hypoglycemics, methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β-blockers, and diuretics. Other topical agents have not been studied with the product and there could be changes in tolerability and absorption of diclofenac. For all of these interactions, as there is only a small percentage of diclofenac absorbed, the risks are likely significantly less than that with oral drug, but the patient and provider should monitor appropriately for these interactions with any of these drugs the patient is taking. Patients should avoid oral NSAIDs while using topical products to minimize additive adverse effects. Care should be taken to avoid contact with the eyes or open wounds and to wash hands after application (except when treating hand OA).

Dosing and Administration

Diclofenac 1% gel (Voltaren®) can be used for hand or knee OA or other joints amenable to topical application (eg, not the hip or shoulder) and is available as an OTC product. It is applied four times daily using the dose measuring cards provided by the manufacturer. Four grams of gel is recommended for application to the affected area in the lower limb (eg, foot, ankle, knee) four times daily. For use on the upper extremities (eg, hand, wrist, elbow), the dose is 2 g four times daily. Diclofenac solution (Pennsaid®), only approved for knee OA, is available as a 2% solution. The 2% diclofenac solution is available in a meter-dose pump. It is applied as two actuations or 40 mg twice daily to the affected knee(s). The entire dose should be pumped into the palm of the hand then applied evenly to the knee. The diclofenac patch (180-mg diclofenac epolamine) is applied twice daily. If the patch doesn't stick well, the patient can tape edges with first-aid tape. Patient counseling is important to carefully explain how to apply the topical products. Other counseling points include hand washing after use, avoidance of touching the eyes, nose, or mouth directly after use, and how long to wait before dressing, putting on gloves, showering, and so forth.

Pharmacoeconomic Impact of NSAIDs

The highest costs associated with the pharmacotherapy of OA are hospitalization for treatment of NSAID-related complications, particularly serious GI adverse events. Historically, gastroprotective therapy or the use of COX-2–selective inhibitors for low-risk patients has not been cost-effective because of the number needed to treat to prevent serious events is large, but most PPIs are generic, multisource products, making concomitant treatment with PPIs effective.[72] Pharmacoeconomic considerations for OA involve the selection of therapy for the initial treatment of patients with OA. Use of the nonprescription analgesic acetaminophen as initial therapy has greatly reduced medication costs in comparison with the use of NSAIDs, many of which are by prescription only. Oral NSAID costs vary considerably, depending on the medication, daily dose, and regimen selected. As oral NSAIDs as a class are therapeutically similar, the use of a less-expensive agent such as nonprescription ibuprofen or naproxen or a multisource generic product may minimize the cost. More expensive NSAIDs can be prescribed if neither of these offers benefit after a 2-week trial at sufficient doses. Prescription-only topical NSAIDs are significantly more costly than oral agents. Over-the-counter diclofenac products are likely to have a similar cost compared to many generic prescription oral NSAIDs. Costs related to the serious complications associated with oral NSAID therapy are likely to outweigh the costs associated with topical diclofenac in any form, making prescription status products cost-effective.

Intra-articular Corticosteroids Pharmacology and Mechanism of Action

⑩ The anti-inflammatory properties of corticosteroids as a class are the primary mechanism of pain relief in the treatment of OA. These properties decrease the formation and release of prostaglandins, kinins, liposomal enzymes, and histamine. These actions decrease erythema, swelling, heat, and tenderness of the inflamed joints.[25,73] Aspiration of the effusion and injection of glucocorticoid are carried out aseptically, with examination of the aspirate recommended to exclude crystalline arthritis or infection. Several randomized, placebo-controlled, double-blind studies have shown that intra-articular corticosteroids are superior to placebo in alleviating knee pain and stiffness caused by OA but with a relatively short duration.[73] The most commonly used corticosteroids for intra-articular use are triamcinolone acetonide and methylprednisolone acetate. The branched esters of triamcinolone and methylprednisolone are preferred by practitioners because of the reduced solubility that allows the agents to remain in the joint space longer.[74,75]

Adverse Events

Adverse events associated with intra-articular injection of corticosteroids can be local or systemic in nature. Systemic adverse events are the same as with any other systemic corticosteroid and can include hyperglycemia, edema, elevated blood pressure, flushing, dyspepsia, and hypercortisolism. There is an acute 2- to 3-day rise in blood glucose in patients with diabetes following a single corticosteroid injection. The risk of systemic side effects can be lessened by limiting the dose of the corticosteroid since doses greater than 40 mg for triamcinolone or methylprednisolone have not been shown to provide any additional benefit.[74] Local adverse effects can include infection in the affected joint, osteonecrosis, tendon rupture, and skin atrophy at the injection site. Systemic corticosteroid therapy is not recommended in OA, given the lack of proven benefit and the well-known adverse effects with long-term use.

Dosing and Administration

Average doses for injection of large joints in adults are 40 mg of triamcinolone and methylprednisolone acetate. Local anesthetics such as lidocaine or bupivacaine are commonly combined with corticosteroids to provide rapid pain relief.[74] This therapy is generally limited to three or four injections per year due to the potential systemic effects of corticosteroids and because the need for more frequent injections indicates little response to the therapy.

After injection, the patient should minimize activity and stress on the joint for several days. Initial pain relief may be seen within 24 to 72 hours after injection, with peak pain relief about 7 to 10 days after injection and lasting up to 4 to 8 weeks.

Capsaicin Pharmacology and Mechanism of Action

Capsaicin, isolated from hot peppers, releases and ultimately depletes substance P from afferent nociceptive nerve fibers. Substance P has been implicated in the transmission of pain in arthritis, and capsaicin cream has demonstrated to have moderate efficacy compared to placebo in clinical trials.[51] Due to the larger surface area and distance from the site of application to the joint, it is not expected that application of capsaicin would provide efficacy in the treatment of hip OA.

Adverse Effects

Adverse events associated with capsaicin are primarily local, including burning, stinging, and/or erythema that usually subsides with repeated application. Systemic effects are rare.[51] The FDA has issued a public drug safety communication notifying consumers that rare cases of severe burns have been reported.[76] Some patients may experience coughing associated with application.

Dosing and Administration

To be effective, capsaicin must be used regularly, and it may take up to 2 weeks to take effect. Use is recommended four times a day.[51] Patients should be counseled not to get the cream in their eyes or mouth. Patients should also notify their healthcare provider immediately if they experience pain, swelling, or blistering skin at the site of application.

Capsaicin is a nonprescription product available as a cream, gel, solution lotion, or patch in concentrations ranging from 0.025% to 0.15%.

Tramadol Pharmacology and Mechanism of Action

Tramadol, an analgesic with affinity for the μ-opioid receptor, as well as weak inhibition of the reuptake of norepinephrine and serotonin neurotransmitter, has shown moderate pain improvement for patients with OA when compared with placebo.[77,78] Tramadol is also modestly effective as add-on therapy for patients taking concomitant acetaminophen, NSAIDs, or COX-2–selective inhibitors. Tramadol may be helpful for patients who cannot take NSAIDs or COX-2–selective inhibitors.

Adverse Events

Opioid-like adverse effects such as nausea, vomiting, dizziness, constipation, headache, and somnolence are common with tramadol. These occur in 45% to 84% of treated patients.[79] Although the frequency of adverse effects is high, the severity of these effects is less than for NSAIDs, as tramadol use is not associated with life-threatening GI bleeding, CV events, or renal failure. The most notable serious adverse event associated with tramadol use is seizures. Withdrawal symptoms can occur if tramadol is stopped abruptly. Older adults are significantly more likely to experience adverse events.[79] Tramadol was initially not classified as a controlled substance but was rescheduled as a class IV controlled substance due to its potential for dependence, addiction, and diversion.

Drug-Drug Interaction

Medications that lower the seizure threshold should be used with caution in patients taking tramadol. These include tricyclic antidepressants, first-generation antipsychotic medications, and cyclobenzaprine, as well as others. There is also an increased risk of serotonin syndrome (see Chapter 88, “Depressive Disorders,” for description) when tramadol is used concomitantly with other serotonergic medications, including duloxetine.

Dosing and Administration

Tramadol should be initiated at a lower dose (100 mg/day) and may be titrated as needed for pain control to a dose of 200 mg/day, with a maximum dose of 400 mg/day. Tramadol is available in a combination tablet with acetaminophen and as an extended-release tablet or capsule.

Second-Line Treatments Opioid Analgesics

Opioid analgesics may be useful for patients who experience limited pain relief with acetaminophen, oral NSAIDs, intra-articular injections, or topical therapy or who cannot tolerate the side effect profile of these agents.[55] For patients with underlying conditions that limit the use of first-line analgesics, opioid analgesics can effectively relieve acute OA pain. A common clinical scenario includes the patient who cannot take oral NSAIDs because of renal failure or CV disease. Patients in whom all other treatment options have failed and who are at high surgical risk, precluding joint arthroplasty, are also candidates for opioid therapy. It is important to carefully use opioids to promote safety. The CDC recommends only prescribing opioids if the benefits from pain control and function outweigh the risk. The best practices for prescribing opioid include using the lowest effective dose and the smallest quantity needed; providing patients with information on how to use, store, and dispose of opioid medications; and avoiding combinations of opioids and sedating medications unless there is a specific indication to do so. Opioid use should be assessed at least every 3 months, evaluating patient progression toward functional treatment goals, risks of harm, and adverse effects.[80]

Adverse effects are common in opioid-treated patients with OA. More than 75% of patients in clinical trials experience at least one typical opioid-related (ie, nausea, somnolence, constipation, dry mouth, and dizziness) adverse effect. Although this is not an unexpected finding, it serves as a reminder to use opioids cautiously in elderly patients who may be more susceptible to adverse effects.

Opioid dependence, addiction, tolerance, hyperalgesia, and issues surrounding drug diversion are more serious adverse effects associated with long-term treatment. Prescription opioid misuse/abuse/addiction is a major public health concern with the CDC reporting around 46 deaths every day from prescription opioid overdose.[81] Patients should be educated on the risks of taking opioids, including addiction, overdose, and death.

If pain is poorly controlled and limits activities of daily living, and the patient has sufficiently good cardiopulmonary health to undergo major surgery, joint replacement may be preferable to continued reliance on opioids.

Duloxetine

Duloxetine is a centrally acting dual-reuptake inhibitor of both serotonin and norepinephrine, although norepinephrine reuptake inhibition does not occur until doses reach 60 mg/day. While the most common pain target in OA is peripheral nociceptive pain, there is some evidence that chronic nociceptive pain leads to central pain sensitization thereby lowering the pain threshold.[47] Duloxetine provides pain relief through the blocking of central pain transmitters, including serotonin and norepinephrine.

Adverse effects commonly associated with duloxetine therapy include nausea, dry mouth, constipation, and anorexia. Expected neurologic adverse effects include fatigue, somnolence, and dizziness. Rare, but serious adverse events associated with duloxetine include Stevens-Johnson syndrome and liver failure. Patients should be notified to contact their healthcare provider immediately if they develop a rash while taking duloxetine.

Particular care should be taken to avoid the use of duloxetine with other serotonergic medications including tramadol. As tramadol is a first-line treatment recommendation for OA, the likelihood of encountering this combination is high. Concomitant use of duloxetine with other medications that increase serotonin concentrations increases the risk of serotonin syndrome.

Hyaluronic Acid Injections

Hyaluronate is a naturally occurring component of cartilage and synovial fluid. Exogenous intra-articular hyaluronate is available as a treatment for the symptoms of knee OA. The goal of intra-articular HA is to provide and maintain intra-articular lubrication. HA may also have anti-inflammatory, analgesic, and chondroprotective effects on the articular cartilage and joint synovium.[82] Evidence has not shown intra-articular HA to have a clinically significant benefit involving pain relief and functional improvement and therefore does not support the routine use of HA.[83] Most HA products are injected once weekly for either 3 or 5 weeks, depending on the specific agent administered. Patients are generally advised to repeat the injection schedule by 6 months if they are satisfied with the previous course.[73] Strenuous or prolonged weight-bearing activities should be avoided for 48 hours after treatment. Routinely, most of the improvement is expected from 5 to 13 weeks after injection with some effect still occurring at 24 weeks.[82] Injections are generally well tolerated, although acute joint swelling, effusion, and stiffness can occur. Local skin reactions, including rash, ecchymosis, and pruritus, have also been reported. Local adverse effects are more frequent in products from animal origin. Rarely, systemic adverse events including hypersensitivity reactions have occurred. Joint infections are rare but have been reported.

At this time, the effect of HA injections on knee OA is modest at best.[82] These agents are expensive because the treatment includes both drug costs and administration costs. Patient expectations and cost effectiveness must be considered before choosing HA injection.[73]

Glucosamine and Chondroitin

Interest in chondroitin and glucosamine was spurred initially by anecdotal reports of benefit in animals and humans and by the ability of these substances to stimulate proteoglycan synthesis from articular cartilage in vitro. Over the past decade, enthusiasm for these agents has waned as additional efficacy data has become available to the point that the American College of Rheumatology conditionally recommends against the use of glucosamine and chondroitin.[25] Glucosamine, alone or in combination, has not been shown to provide uniform improvements in pain control or functional status in patients with OA of the knee or hip.[84]

Numerous trials have examined the safety and efficacy of glucosamine and chondroitin; however, the duration of these studies has been relatively short. The efficacy of glucosamine and chondroitin was evaluated after 2 years and was found not to be statistically superior to placebo.[85] The combination of glucosamine and chondroitin was well tolerated. There has previously been some concern that glucosamine may worsen diabetes or asthma; however, with 2-year follow-up this was not substantiated.[85] When the combination of glucosamine and chondroitin was compared to celecoxib in patients with knee OA, it was noninferior in the reduction of pain at 6 months. The combination was well tolerated and the authors suggest glucosamine and chondroitin as a potential safe alternative for patients with CV or GI conditions.[86]

Because glucosamine and chondroitin are marketed in the United States as dietary supplements, neither the products nor their purity is adequately regulated by the FDA. The potential consequences related to the lack of regulatory oversight for these products can affect both efficacy and safety. Products containing less than labeled doses can compromise efficacy, while those containing ingredients not included on the labeling can compromise safety. A variety of brand name and generic products are available in various doses and formulations.

EVALUATION OF THERAPEUTIC OUTCOMES

For persons with OA, treatment decisions and pharmacotherapy monitoring is patient specific. The patient's situation and individual needs should be considered when devising a treatment plan. Is the patient bothered primarily by pain, by limitations in activity, or with concerns about side effects from medications? Does the patient understand what OA is and why certain treatments are useful?

When the patient is first being assessed for the possibility of OA, the diagnosis is often straightforward, including history and physical exam, plain films of the affected joint(s), and lab tests. The older patient with unilateral knee pain, limited range of motion, no palpable warmth, crepitus, and without prolonged morning stiffness and other suspicious findings is highly likely to have knee OA. It is still reasonable to obtain x-rays that may help follow disease over time (although joint space narrowing often does not correlate with the extent of pain or difficulty walking). Basic labs to help decide what pharmacologic therapy is possible (eg, no NSAIDs with poor renal function), assessment of pain using a visual analog scale, range of motion for affected joints. Additional tests of OA severity may include measurement of grip strength, 50 ft (~15 m) walking time, patient and physician global assessment of OA severity, and assessment of ability to perform activities of daily living. Once the patient is assessed and diagnosed, patient and family education is essential. Nondrug therapy may include a referral for physical and/or occupational therapy services, where the therapists can help to maintain and improve range of motion. Referral for nutritional counseling and weight loss may also be necessary if the patient is overweight or obese. These interventions may decrease pain and facilitate improved activity for OA patients.

Although all patients must be provided with nonpharmacologic therapies, results from these interventions usually require weeks to months. In the meantime, the patient needs pain relief. First-line therapy continues to be acetaminophen. Adverse events with acetaminophen are uncommon, although it is important that the patient understand the maximum daily dose limits and all possible sources of acetaminophen-containing products. Although some do well on acetaminophen, many do not achieve sufficient pain relief. A step up to oral NSAIDs or second-line therapy might be necessary but poses significant risks beyond acetaminophen. A switch to NSAIDs requires careful consideration of the patient's age and comorbidities, renal function, history of GI problems, hypertension, and CV health. Periodic monitoring would include open-ended questions followed by direct questions relating to the commonest adverse effects associated with the respective medication. For an oral NSAID, symptoms of abdominal pain, heartburn, nausea, or change in stool color provide valuable clues to the presence of GI complications, although serious GI complications can occur without warning. Patients should be monitored for the development of hypertension, weight gain, edema, skin rash, and CNS adverse effects such as headaches and drowsiness. Baseline serum creatinine, complete blood count, and serum transaminases are repeated at 6- to 12-month intervals to identify GI, renal, and hepatic toxicities.

Topical NSAIDs have demonstrated efficacy in OA of the hand and knee and are as effective as oral NSAIDs. Although they carry the same CV, renal, and GI warnings, their area under the concentration–time curve (AUC) for a typical dose is only a few percent of the AUC from an equivalent dose of oral NSAID. Topical NSAIDs' most common side effects are local, with irritated skin, rash, or itching, usually mild, and with many fewer adverse effects of CV, GI, or renal nature. These agents are a welcome addition to the limited treatment modalities for the common, costly, painful, and often disabling disease of OA. It is important that the patient apply the topical products appropriately to achieve maximum benefit and avoid adverse events.

For patients receiving intra-articular corticosteroids, pain relief should begin with 2 to 3 days and last 4 to 8 weeks. Patients should be advised about possible injection site reactions, as well as possible systemic effects, especially for those with hypertension or diabetes, as there is a potential for increased blood pressure or blood glucose. For patients receiving opioids or tramadol, relief from pain should occur rapidly. Frail or elderly patients should be monitored carefully and cautioned about sedation, dysphoria, nausea, risk of falls, and constipation. Special additional monitoring should include strategies to assess development of opioid tolerance, addiction, misuse, and diversion.

CONCLUSION

OA is a common, slowly progressive disorder that affects diarthrodial joints and is characterized by progressive deterioration of articular cartilage, subchondral sclerosis, and osteophyte production. Clinical manifestations include gradual onset of joint pain, stiffness, and limitation of motion. The primary treatment goals are to reduce pain, maintain function, and prevent further destruction. An individualized approach based on education, rest, exercise, weight loss as needed, and analgesic medication can succeed in meeting these goals. Recommended drug treatment starts with acetaminophen ≤4 g/day and topical analgesics as needed. If acetaminophen is ineffective, oral NSAIDs may be used in appropriately selected patients, often providing satisfactory relief of pain and stiffness. Individuals at increased risk for toxicity from NSAIDs, especially for GI, CV, or renal events, deserve special attention. Celecoxib may have safety advantages in some OA patients, but its safety relative to other NSAIDs and its role in OA remains poorly defined. Adjunctive therapy with tramadol, intra-articular corticosteroids, and duloxetine may be helpful in patients with poorly controlled pain. Experimental therapy aimed at preventing the progression of OA requires further clinical investigation before entering widespread clinical use.

SELF-ASSESSMENT QUESTIONS

1. Risk factors for the development of osteoarthritis (OA) include:
    - A. Smoking
    - B. Participation in running
    - C. Being underweight
    - D. Advanced age
    - E. B and D
2. Patient education for OA, such as programs in which volunteers regularly contact patients:
    - A. Has not yet been demonstrated to provide benefit to OA patients
    - B. Is too expensive to recommend for general use by OA patients
    - C. Should emphasize the “wear and tear” nature of OA as part of the educational message
    - D. Has been shown to improve pain and functional status of OA patients
    - E. All of the above
3. Matrix metalloproteinases (MMPs):
    - A. Are naturally occurring chemokines that work primarily by recruiting neutrophils and macrophages to the inflamed synovium
    - B. Help trigger degradation of articular cartilage by cleaving peptide bonds in proteoglycans
    - C. Are stimulated by tissue inhibitors of metalloproteinases (TIMPS)
    - D. Must be activated before they can ease the pain of OA
    - E. B and C
4. Which of the following are required for an accurate and appropriate diagnosis of OA?
    - A. Patient history and physical examination
    - B. Patient history, physical examination, and radiologic evaluation
    - C. Physical examination and magnetic resonance imaging
    - D. Patient history, physical examination, and positive response to pharmacologic treatment
    - E. Any of the above is accurate and appropriate
5. Acetaminophen:
    - A. Is recommended as an appropriate initial treatment in OA
    - B. Should be given on a scheduled basis for optimal pain control
    - C. Can be associated with hepatotoxicity at doses below 4 g/day

D. Provides mild analgesia

E. All of the above

6. Traditional, nonselective nonsteroidal anti-inflammatory drugs (NSAIDs):

A. Block access of arachidonic acid to both COX-1 and COX-2 enzymes

B. Promote platelet aggregation through blockade of COX-2 activity

C. Promote prostaglandin and bicarbonate production in gastric mucosa through blockade of COX-2 activity

D. Counteract renal vasoconstriction by promoting formation of renal prostaglandins

E. Are anti-inflammatory at low doses and analgesic at higher doses

7. NSAIDs:

A. Are associated with thousands of serious or life-threatening GI adverse events every year

B. Provide superior relief of OA pain in some individuals

C. Will usually produce symptoms of dyspepsia or abdominal discomfort as a prelude to serious GI adverse events

D. When used in anti-inflammatory doses, should be consistently monitored by serum levels

E. A and B

8. NSAIDs:

A. Are recommended as an alternative to acetaminophen for controlling inflammation associated with OA

B. Provide pain relief by the inhibition of prostaglandins

C. Provide cardioprotective effects similar to aspirin

D. Increase renal blood flow, causing sodium and potassium excretion

E. B and C

9. Celecoxib, a COX-2 selective inhibitor:

A. Blocks the COX- 2 enzyme with little or no inhibition of COX-1

B. Is more effective at relieving pain than nonselective NSAIDs

C. Is much safer to use in patients with cardiovascular disease

D. Carries a manufacturer's warning against use in sulfa allergic patients

E. A and D

10. Intra-articular corticosteroids:

A. Have no role in OA, as this disease does not have any inflammatory component

B. Are recommended as maintenance therapy for patients who cannot tolerate NSAIDs and who have severe OA

C. Can be administered up to 12 times per year for the treatment of severe OA pain

   D. Are associated with hyperglycemia in patients without diabetes mellitus

   E. Should not be used for the treatment of hip OA

11. Hyaluronic acid injectable material:

   A. Is made using recombinant technology

   B. Provides a long-term increase in viscosity of synovial fluid

   C. Is a low cost pharmacologic therapy

   D. Is highly effective when compared to placebo vehicle injections

   E. Is less effective than intra-articular corticosteroids

12. Recommended treatment options for hip and knee OA patients who have failed acetaminophen include:

   A. Nonselective NSAIDs used at analgesic doses, if the patient is not at high risk for GI bleeding

   B. Nonselective NSAIDs with an H2 antagonist to prevent GI bleeding in the high-risk patient

   C. COX-2 selective inhibitors with sucralfate in the high-risk patient

   D. COX-2 selective inhibitors with misoprostol in the high-risk patient

   E. None of the above

13. Knee replacement surgery should be considered in the patient with OA:

   A. If the patient prefers not to try oral medications such as acetaminophen

   B. If there is significant disability and interference with daily functioning

   C. If the patient refuses treatment with low-dose NSAIDs

   D. If the patient is at high risk for NSAID-related GI bleeding

   E. If the patient does not respond to topical therapy with NSAIDs

14. Topical capsaicin therapy for the treatment of OA pain:

   A. Produces systemic adverse effects

   B. Provides therapeutic results within 48 hours

   C. Is most effective when used on an as-needed basis

   D. Must be used three times daily for best results

   E. Is most appropriate for the treatment of hand OA

15. Which of the following patients is best suited to opioid analgesic therapy for their OA symptoms that have failed scheduled acetaminophen dosing?

   A. History of alcoholism

   B. History of small bowel obstruction

C. History of traumatic fall on home stairs

D. History of myocardial infarction

E. History of poor adherence to medications

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Participation in sports and advancing age are both independent risk factors for the development of OA. Refer to "Etiology" section.

2. **D.** A variety of patient education programs have been shown to improve pain and function in OA patients, including volunteer programs. Refer to "Nonpharmacologic Therapy" section.

3. **B.** MMPs are an important catalyst to normal cartilage turnover and repair. Refer to "Normal Cartilage" ("Function, Structure, and Composition of Cartilage") section.

4. **B.** A patient history to elicit symptoms, a physical exam to examine the affected joint, and basic x-ray examination to review for signs of joint space narrowing and other signs of osteoarthritis are the elements needed to diagnose osteoarthritis. Refer to "Diagnosis" section.

5. **E.** Acetaminophen is guideline-recommended, first-line therapy for all types of OA. Due to short duration of action, scheduled dosing is optimal. The most important toxicity is hepatoxicity. Refer to "Drug Class Information" ("Acetaminophen") section.

6. **A.** The mechanism of action of NSAIDs is the blockade of both COX-1 and COX-2. Refer to "Drug Class Information" ("Oral Nonsteroidal Anti-inflammatory Drugs [Pharmacology and Mechanism of Action]") section.

7. **E.** Due to the mechanism of action, risks of GI adverse events are inherent to NSAID use. Some patients are at higher risk of serious GI adverse events than others. Due to interpatient variability in response to analgesics, some patients have superior relief with NSAID use. Refer to "Drug Class Information" ("Oral Nonsteroidal Anti-inflammatory Drugs [Adverse Effects]") section.

8. **B.** Prostaglandins can generate pain signals. NSAIDs inhibit prostaglandins. Refer to "Drug Class Information" ("Oral Nonsteroidal Anti-inflammatory Drugs [Pharmacology and Mechanism of Action]") section.

9. **E.** Celecoxib is a COX-2 selective NSAID and as such has little to no inhibition of COX-1 enzyme. It also has a sulfonamide chemical structure, leading to a warning against use in sulfa allergic patients. Refer to "Drug Class Information" ("Oral Nonsteroidal Anti-inflammatory Drugs [Pharmacology and Mechanism of Action and Drug-Drug Interactions]") sections.

10. **D.** Intra-articular corticosteroids are associated with the same toxicities as systemic corticosteroids, including hyperglycemia in patients with and without preexisting diabetes mellitus. Refer to "Intra-articular Corticosteroids" ("Adverse Events") section.

11. **E.** Hyaluronic acid injections are less effective than other therapies; in some studies, no more effective than placebo. Refer to "Drug Class Information" ("Hyaluronic Acid Injections") section.

12. **A.** After acetaminophen failure, the next step in therapy is nonselective NSAIDs alone in a patient not at high risk for GI bleeding. H2 antagonists are not effective at preventing GI bleeding in high-risk patients and COX-2 selective inhibitors do not offer a therapeutic advantage in a low-risk patient. Refer to "Drug Class Information" ("Oral Anti-inflammatory Drugs [Adverse Effects (Gastrointestinal Effects of Nonselective NSAIDs)]") section.

13. **B.** Surgery is the best therapeutic option to improve significant disability and interference with activities of daily living. Refer to "Nonpharmacologic Therapy" ("Surgery") section.

14. **E.** Topical capsaicin is guideline-recommended alternative first-line therapy for hand OA. Refer to "Hand OA, First-Line Treatments and Drug Class Information" ("First-Line Treatments [Capsaicin]") section.

15. **D.** All NSAIDs are contraindicated in a patient with a history of a myocardial infarction. Refer to adverse effects under "Drug Class Information" ("Second-Line Treatments [Opioid Analgesics]") section.

Chapter 111: Rheumatoid Arthritis

Stephanie Gruber; Bianca Lezcano; Susan Hylland

KEY CONCEPTS

KEY CONCEPTS

①The etiology of rheumatoid arthritis is unknown but is thought to result from a combination of genetic and environmental factors.

②Rheumatoid arthritis is a systemic autoimmune condition in which inappropriate activation of innate and adaptive immune responses cause inflammation leading to bone, cartilage, and synovium erosion.

③The primary goal of treatment includes targeting disease remission/low disease activity ultimately aiming at enhancing quality of life.

④Care should be provided by a rheumatology-trained clinician.

⑤Optimizing mental health and completing physical therapy are both crucial nonpharmacologic therapies in addition to providing comprehensive disease and treatment education.

⑥Drug treatment should be started as soon as a diagnosis is established.

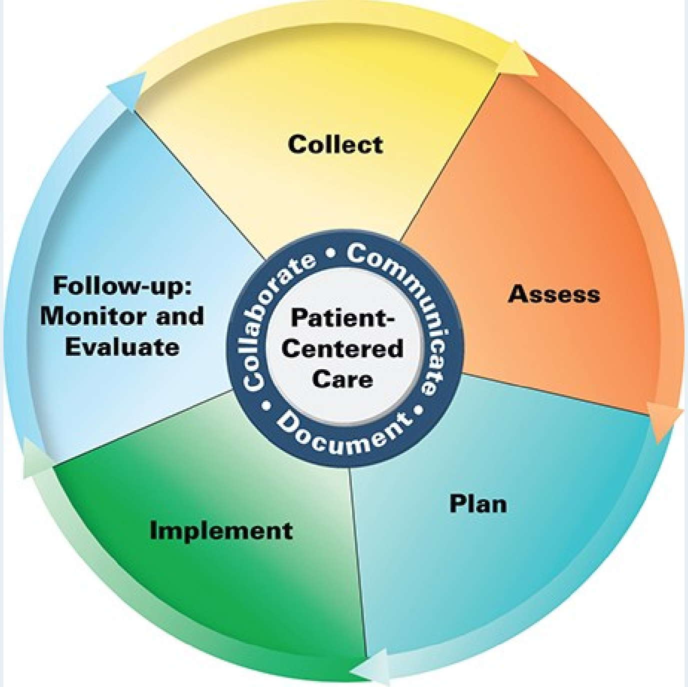
⑦Choice of therapy depends on the level of disease activity, comorbid health conditions, patient preference, and often insurance coverage.

⑧Nonsteroidal anti-inflammatory drugs, analgesics, and corticosteroids are used as adjunctive therapy to disease-modifying antirheumatic drug therapy.

⑨Response to therapy is evaluated by patient subjective reports, physical examination, laboratory markers, and imaging.

PATIENT CARE PROCESS

Patient Care Process for Rheumatoid Arthritis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status, insurance)
- Social history (eg, tobacco/alcohol use, activity)
- Patient medical history (eg, health conditions, immunizations, recent infections)
- Family medical history (eg, autoimmune conditions)
- Current medications
- Past RA medication trials
- Subjective symptom report
- Objective data such as blood pressure, labs (eg, ESR, CRP, CBC), imaging (eg, DEXA, x-ray films, ultrasound), physical examination (eg, number of tender/swollen joints)

Assess

- Patient subjective report (eg, pain score, duration of morning joint stiffness, adherence to therapy, injection technique/medication storage, side effects to drug therapy, disability, fatigue)
- Change in number of tender/swollen joints, labs, or imaging
- Cardiovascular risk factors
- Infection risk and upcoming procedures
- Patient treatment preference (utilize motivational interviewing as appropriate)

Plan*

- Drug therapy (see Table 111-2)
- Referrals when appropriate (eg, tobacco treatment clinic, podiatry, mental health, social work, physical and/or occupational therapy)
- Patient education (eg, dosing, side effects, infection risk management, symptom self-monitoring)
- Order follow-up labs based on therapy chosen (see Table 111-4)

Implement*

- Provide patient education regarding rationale for and follow-up of treatment plan
- Provide patient with written medication changes, time frame for follow-up, and clinic/emergency contact information
- Coordinate and schedule follow-up

Follow-up: Monitor and Evaluate

- Subjective symptom changes and impact on daily activities
- Presence of adverse effects and infections
- Laboratory results as indicated for therapy
- Patient adherence to treatment plan
- Time frame dependent on treatment plan (generally every 1-3 months)

**Collaborate with a rheumatologist.*

BEYOND THE BOOK

BEYOND THE BOOK

Direct-to-consumer advertising refers to the marketing of products to patients rather than healthcare professionals. This is a common marketing strategy, particularly for pharmaceutical products. Watch the following advertisements for tofacitinib and adalimumab:

- https://www.ispot.tv/ad/O1Z1/xeljanz-mornings-raking
- https://www.ispot.tv/ad/wrWz/humira-food-drive.

Reflect on the promotional materials by considering the following questions:

- What is the general feeling generated by the commercials?
- What actions or activities do the commercials focus on?
- What additional concerns might one have after hearing about the possible side effects of this biologic product?

Watching the adalimumab commercial would lead patients to the product website to do their own research: https://www.humira.com. Explore the website and reflect on the following questions:

- How user-friendly is the website? What resources are available for patients?
- What specifically is HUMIRA Complete?
- Where is the injection education video located on the website?
- Would you direct patients to watch this video?
- What resources would you use from this website, if any, for your patient education in clinic?

One of the counseling points for adalimumab is to contact your provider prior to having any surgeries or receiving any vaccinations. Make a chart of which immunizations a patient can and cannot receive while using this injectable medication.

INTRODUCTION

Autoimmune conditions cause the body to produce an inappropriate immune response against its own healthy tissue. Rheumatoid arthritis (RA) is a common, chronic, progressive autoimmune condition that primarily affects the joint and synovium but can also have detrimental effects on organ systems throughout the body. It can have substantial and devastating effects on one's ability to function and complete basic activities of daily living. The exact etiology of RA is unknown, but treatment options are numerous. Comprehensive treatment plans are developed under the guidance of a rheumatology specialist and through a process of shared decision-making with the patient.

EPIDEMIOLOGY

RA is one of the more common autoimmune conditions. The annual incidence is about 40 individuals per 100,000. Worldwide disease prevalence is approximately 1% with some variance for race and geographic location.[1] This prevalence corresponds most closely with North American and Northern European countries; however, native American-Indian populations have the highest prevalence noted (approximately 5%-6%). Southern European, Eastern Asian, and African countries have a lower prevalence.[1] Women are twice as likely to develop the disease compared with men.[2]

RA generally presents in the fifth decade of life with increasing prevalence up to the eighth decade of life.[3] RA can affect children age 16 years or younger; in these patients, the condition is referred to as juvenile RA. This chapter focuses only on the clinical management of adult RA. Compared with the general population, individuals with RA have higher rates of disability claims and workplace limitations and lower rates of employment.[4] Loss of productivity has been associated with lower annual earnings.[2,4]

The mortality rate in patients with RA is higher than that of the general population. Cardiovascular (CV) disease is the leading cause of death in RA and presents the greatest concern. Patients with RA have a higher risk of major adverse CV events, and RA disease activity is a predictor of increased CV risk. The risk of death is also increased by infections, malignancy, depression, and pulmonary disease. The expected life expectancy of patients with RA is 3 to 10 years less than the general population.[5–7]

Despite advancements in therapy, mortality trends have not changed drastically, though one could argue additional time is required to detect changes in survival data. Other common comorbid autoimmune diseases include insulin-dependent diabetes mellitus and autoimmune thyroid disease.[6,7]

ETIOLOGY

① The specific cause of RA is unknown. The disease results from a mix of genetic susceptibility and nongenetic factors combined with a triggering event. Genetic polymorphisms seem to play a large role based on descriptive epidemiologic studies. There is a thought that multiple genes are involved, specifically those of the human leukocyte antigen (HLA) system.[8] Genetics also seems to play a role based on familial studies. In studies of the development of RA in twins, monozygotic twins had a higher concordance than dizygotic twins.[9] Patients with a first-degree relative with RA are at a higher risk of having RA themselves when nongenetic factors are standardized.[10]

There is some variability regarding the role of hormonal regulation and the likelihood of RA development, particularly with estrogen. Evidence is conflicting as to whether pregnancy status affects the risk of RA. Pregnancy is often associated with disease remission in the last trimester, but flares commonly occur in the acute postpartum period.[8] There is also controversial evidence showing female oral contraceptives may protect against or postpone disease development. Testosterone may have a protective effect, as men with low testosterone levels are more likely to have RA.

Nongenetic or environmental factors possibly associated with RA include cigarette use, coffee consumption, and obesity.[8] Cigarette smoking has been tied to increased disease activity, increased biomarkers, and poor prognoses.[6] Ties are weaker for disease development with heavy coffee consumption and obesity.[11,12] Dietary choices have been reported by patients to both positively and negatively impact disease severity or progression.[13] Occupational hazards, such as exposure to silica, may also play a role in susceptibility to disease.[14]

Additional factors, aside from those mentioned above, are needed to trigger the disease itself. An infectious process is hypothesized to be the primary trigger. The Epstein–Barr virus and retroviruses are most commonly associated with the disease.[8] Infections of *Mycoplasma* spp. and *Porphyromonas gingivalis* have been suspected as bacterial triggers, but no true link has been found to show their causality.[15] Further studies are required to help uncover the exact etiology of RA.

PATHOPHYSIOLOGY

② The role of the immune system is to detect foreign matter, build a response, and neutralize the threat. In RA, the immune system cannot discriminate between self and nonself. This results in cell proliferation, inflammation, and destruction of tissues and fluids throughout one's own body.

The immune cascade and inflammatory pathway dysregulation associated with RA is multifactorial (Fig. 111-1). Overstimulation of the innate immune system is thought to be one of the earliest histologic changes in RA. T cells display an activated surface phenotype with high allele expression of HLA and CD 27, increasing their affinity for lymphokines. Activated T cells stimulate B cells, causing production of autoantibodies. These autoantibodies form large complexes that deposit throughout the body. Antibodies to immunoglobulin G (IgG) have a strong correlation to the pathogenesis and poor prognosis of RA and are known as rheumatoid factor (RF). B cells also produce proinflammatory cytokines, including tumor necrosis factor (TNF) and the interleukin (IL) system, which are responsible for inducing expression of adhesion molecules on the endothelium, further enhancing T-cell proliferation and differentiation, encouraging cell migration, and regulating matrix modeling.[16–18]

FIGURE 111-1

Pathogenesis of the inflammatory response. Antigen-presenting cells process and present antigens to T cells, which may stimulate B cells to produce antibodies and osteoclasts to destroy and remove bone. Macrophages stimulated by the immune response can stimulate T cells and osteoclasts to promote inflammation. They also can stimulate fibroblasts, which produce matrix metalloproteinases to degrade the bone matrix and produce proinflammatory cytokines. Activated T cells and macrophages release factors that promote tissue destruction, increase blood flow, and result in cellular invasion of synovial tissue and joint fluid. (APC, antigen-presenting cell; IL, interleukin; MMP, matrix metalloproteinase; TNF-α, tumor necrosis factor α)

Other mechanisms of pathogenesis include overexpression of tumor suppressor gene *p53*, which prevents normal DNA repair and interferes with appropriate cell apoptosis (programmed cell death), and increased presence of anticitrullinated protein antibodies (ACPA). ACPA positivity is associated with a poorer prognosis in patients with RA.[19,20]

A variety of histological changes occur within the synovium, given the above pathological processes. Synovial tissue typically attaches to the skeletal tissues and the bone-cartilage joint cavity and provides a protective shield for the synovial interstitium and a nutrient-rich environment for cartilage. Migration of lymphocytes, macrophages, and mononuclear cells into the synovium and synovial cavity are some of the earliest histologic changes in RA. With the increased mass to the synovium comes hypertrophy and subsequently angiogenesis, which is needed to bring the necessary oxygen and nutrients to the environment. Angiogenesis is initiated by the proinflammatory cytokines and driven by factors such as IL-8, prostaglandins, vascular endothelial growth factor, and macrophage angiogenic factor. As the vessels develop, cytokines also stimulate further migration of both innate and adaptive immune systems into the synovium, causing inflammation. The inflamed, fibrotic synovium found in RA is known as a pannus. The pannus invades cartilage and bone around it, thereby promoting further destruction and dysregulation.[21–24]

Cytokines in the cartilage drive the generation of reactive nitrogen and oxygen species while increasing chondrocyte catabolism, inhibiting chondrocyte anabolism, and increasing extracellular matrix destruction. Proinflammatory cytokines travel to the bone, provide the source for receptor activator of NFkB ligand (RANKL), and enhance the differentiation and activity of osteoclasts leading to bone matrix destruction.[25–28]

Circulating immune complexes and T cells have been found in the extra-articular involvement of RA. Chronic inflammation in vascular endothelial and visceral, cutaneous, and pleural tissues leads to complications including vasculitis, fibrosis, anemia, and renal amyloidosis.[21,29]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Rheumatoid Arthritis

Joint Involvement

- Hands, wrists, ankles, and feet are most commonly affected, often bilaterally
- Presence of warmth and swelling with or without pain
- Prolonged morning stiffness, often for longer than 30 minutes in duration
- Decreased functionality
- Symptoms present for 6 weeks or more
- Subluxations and deformities possible with advanced disease

Extra-articular Involvement

- Generalized fatigue, weakness, and decreased mood are nonspecific implications of disease
- Rheumatoid nodules can be found on extensor or pleural lining surfaces
- Interstitial lung disease or pleural disease
- Vasculitis
- Keratoconjunctivitis sicca, scleritis, or Sjögren’s syndrome
- Pericarditis, cardiac conduction abnormalities, or myocarditis
- Felty syndrome or anemia

Laboratory Findings

- Rheumatoid factor is detected in 70% to 80% of patients with RA with higher titers, which reflects increased sensitivity and more progressive disease
- Anticyclic citrullinated antibodies are more specific for disease, particularly early stage, and generally indicate more aggressive disease
- Erythrocyte sedimentation rate and C-reactive proteins may indicate the presence of a nonspecific inflammatory process
- Synovial fluid analysis through joint aspiration typically demonstrates a high white blood cell count in the absence of crystals or infection

Radiography

- In early stages of RA, it may show soft tissue swelling and joint space narrowing
- In late-stage disease, it may show joint subluxations, deviations, and secondary arthritis

Joint Involvement

Patients with RA often present with involvement of synovial-lined peripheral joints, typically in a symmetrical fashion (Fig. 111-2). The joints of the hands, feet, wrists, and ankles are most commonly involved. Elbows, knees, shoulders, hips, cervical spine, and temporomandibular joints may also be affected.

FIGURE 111-2

Patterns of joint involvement in rheumatoid arthritis.

Classic features of RA are the presence of swelling and prolonged morning stiffness, often for more than 30 minutes. Joint swelling is caused by proliferation of synovium or effusion within the joint capsule. On physical examination, joint swelling may be visible or detected by palpation of soft spongy tissue along joint lines. A swollen joint may appear erythematous, and the overlying skin may feel warmer than surrounding tissue. In contrast, the swelling associated with osteoarthritis is due to bony enlargement and not typically associated with signs of inflammation.

RA of the hands more specifically involves the metacarpophalangeal, proximal interphalangeal, and wrist joints, while sparing distal interphalangeal joints (Fig. 111-3). Pain and swelling commonly affect joint range of motion and grip strength. Wrist swelling may lead to focal nerve compression, causing symptoms of carpal tunnel syndrome. Untreated, long-term joint inflammation may lead to bony erosions, subluxations, and deformities (Figs. 111-4 and 111-5). These changes may alter the mechanics of hand function, reducing grip strength and making it difficult to perform usual daily activities.

FIGURE 111-3

Typical hand deformities of rheumatoid arthritis showing ulnar deviation of the fingers and swelling of the metacarpophalangeal and proximal interphalangeal joints. When patients with RA have involvement of the joints of the feet, walking may be difficult because of metatarsophalangeal, midfoot, and ankle joint inflammation. Untreated long-term inflammation may lead to subluxations of the metatarsal heads causing bunion formation, hammer toe deformities, or overlapping digits (Figs. 111-4 and 111-5). Affected joints are then subject to ulceration of the skin overlying joint deformities secondary to pressure caused by footwear.

Other parts of the body are also affected by pathophysiologic changes in RA. Pain and decreased range of motion in the elbow and shoulder joints may be the result of joint inflammation or inflammation of the tendons and bursae around the joints. Chronic synovial inflammation of the knee may lead to effusions, pain, and loss of range of motion. Synovitis of the knee may cause the formation of a fluid collection behind the knee called a popliteal (Baker) cyst. Eventually, chronic knee joint inflammation may lead to cartilage loss and muscle atrophy, which can result in laxity of the ligamentous structures that support the knee and ultimately instability. The hip joint, a large axial joint, is less commonly involved in RA, but may manifest with joint effusion and long-term accelerated cartilage loss.

Spinal involvement in RA, when present, occurs in the upper cervical vertebrae. Inflammation of the synovial-lined portions of the first and second cervical vertebrae (C1-C2) can lead to neck pain and stiffness. Long-term RA activity at this joint may lead to instability and subluxation, putting patients at risk for spinal cord compression, although this complication is rare.

The temporomandibular joint of the jaw is also a synovial lined joint and, when affected, patients with RA may experience malocclusion and difficulty chewing.

Extra-articular Involvement

Although joint involvement is the hallmark finding in RA, it is important to recognize that this is ultimately a multisystem inflammatory disease. Patients with high-titer RF or ACPA have a higher likelihood of extra-articular manifestations.

Rheumatoid Nodules

Rheumatoid nodules occur in 20% to 35% of patients with RA at some point during their disease course.[30] Rheumatoid nodules are subcutaneous collections of palisading macrophages surrounded by lymphocytes and fibroblasts, which can vary in size from several millimeters to several centimeters. They are most commonly found on the extensor surfaces of the elbows, forearms, and hands but also may be seen on the feet and at other pressure points. They also may develop in the lung or pleural lining of the lung. Rheumatoid nodules usually are asymptomatic and do not require any special intervention. They do not necessarily improve with treatments targeting RA activity and can accelerate in growth during treatment with methotrexate.[31]

Pulmonary Complications

Interstitial lung disease (ILD) is the most common pulmonary manifestation of rheumatoid disease. Frequently ILD is not overtly clinically apparent, but it can be seen on high-resolution CT imaging in up to 33% of patients with RA without symptoms of cough or dyspnea.[32] The most frequent patterns of ILD seen in RA are the usual interstitial pneumonia and nonspecific interstitial pneumonia. Smoking increases the risk of this complication.[33]

Pleural disease is common in RA, and while most commonly asymptomatic, it may result in pleural effusion.[34] Rheumatoid nodules may also develop in lung tissue and may be difficult to distinguish from infection or malignancy on chest imaging. Interstitial pneumonitis is a rare but potentially life-threatening complication of RA. Treatments directed at treating articular manifestations of rheumatoid arthritis frequently do not control pulmonary manifestations.

Vasculitis

Rheumatoid vasculitis is a rare complication of RA seen in patients with long-standing seropositive disease. Invasion of arterial walls by inflammatory cells results in narrowing of the vessel lumen, producing tissue ischemia and infarct. Skin is the most common tissue involved, and infarcts of distal fingers or toes are usually of little consequence. Vasculitis may also involve skin in the lower extremities, producing ulcers that may first appear to be stasis ulcers but are painful due to the ischemic arterial component.

When more severe or visceral rheumatoid vasculitis is present, patients commonly show constitutional symptoms such as weight loss, fever, or failure to thrive. Infarction of vessels supplying blood to nerves can cause motor deficits, such as a foot drop. Renal involvement of vasculitis may lead to a necrotizing glomerulonephritis. Rarely, involvement of medium-sized vessels can result in life-threatening complications with visceral involvement similar to that seen in polyarteritis nodosa.

Rheumatoid vasculitis requires aggressive immunosuppressive therapy to prevent serious complications. Fortunately, the incidence of rheumatoid vasculitis has dramatically decreased with the advent of the routine use of disease-modifying antirheumatic drugs (DMARDs) and biologic therapies with the intent of treating patients with RA to target remission.[35]

Ocular Manifestations

Ocular manifestations of RA include keratoconjunctivitis sicca and inflammation of the sclera, episclera, cornea, and uveal tract. Inflammation and subsequent atrophy of the lacrimal glands may result in decreased tear formation, causing dry and itchy eyes, a condition usually termed *keratoconjunctivitis sicca*. When this condition is observed in association with RA, it is referred to as “secondary Sjögren’s syndrome.”

Inflammation of the superficial layers of the sclera is called *episcleritis* and is a generally self-limiting manifestation. *Scleritis* is a more serious vascular inflammation of the cornea, episclera, and uvea, as it is painful and threatens vision. Scleritis in RA is typically a sign of uncontrolled systemic inflammation and warrants prompt and aggressive immunosuppression to preserve vision.

Cardiac Involvement

RA is believed to be an independent risk factor for coronary artery disease and is associated with an increased risk of cardiovascular mortality. A meta-analysis published in 2008 concluded that the risk of cardiovascular mortality was 59% higher in patients with RA than in the general population.[36]

The risk for cardiovascular disease is higher in those with more active inflammation and is reduced with treatment, particularly with methotrexate.[37] Pericarditis may occur, although the development of clinically evident pericarditis with tamponade is a rare complication. Cardiac conduction abnormalities and aortic valve incompetence, caused by aortic root dilation, may occur. Myocarditis is a rare complication of RA.

Hematologic Involvement

A small subset of patients with more severe, long-standing, seropositive RA will go on to develop splenomegaly and neutropenia; this is known as *Felty syndrome*. Neutropenia leads to an increased susceptibility to recurrent bacterial infection. Treatment with immunosuppressive therapy, typically methotrexate, with the goal of reversing immune system dysfunction, will usually improve granulocyte counts.

Large granular lymphocyte leukemia (LGL) is an indolent leukemia characterized by a clonal proliferation of large granular lymphocytes. Often patients with LGL require no therapy, unless neutropenia is severe leading to recurrent infections. LGL is treated with immunosuppression. The majority of experience has involved the use of methotrexate, cyclophosphamide, or cyclosporine.[38]

Other Complications

Lymphadenopathy may occur in patients with RA, and when present, it warrants a work-up for infection or malignancy. Amyloidosis is a rare complication of longstanding RA and may lead to renal and gastrointestinal complications. Osteoporosis in patients with RA is almost two times higher than in patients without RA.[39]

Laboratory Findings

The complete blood count can be altered by RA or its treatment. A mild-to-moderate normocytic anemia is commonly due to anemia of chronic disease. It is important to differentiate anemia of chronic disease from anemia associated with complications of therapy, such as gastritis induced by nonsteroidal anti-inflammatory drugs (NSAIDs) or bone marrow suppression from immunosuppressive therapy. Thrombocytosis is a common finding with active RA since platelets are generally considered an acute phase reactant and tend to rise and fall in correlation with inflammation in many patients. Thrombocytopenia may also result as a side effect of immunosuppressive therapy. Neutropenia is associated with Felty syndrome and LGL, but it also may be a side effect of immunosuppressive drugs. Leukocytosis is seen commonly as a result of corticosteroid treatment.

The erythrocyte sedimentation rate (ESR) and C-reactive proteins (CRP) are nonspecific markers of inflammation that are usually elevated in patients with active RA. They may be used as an aid in following RA activity.

A positive RF is detected in 70% to 80% of patients with RA. In general, higher titers of RF increase the sensitivity and indicate a potentially more severe disease course. A positive RF (two times the upper limit of normal) in a patient with consistent clinical features of inflammatory arthritis is fairly specific for rheumatoid arthritis. However, a positive RF, especially with a low titer in a patient without clinical evidence of inflammatory arthritis, has low specificity for RA. Many patients with hepatitis C have a positive rheumatoid factor, as do many patients with Sjögren’s syndrome, sarcoidosis, and certain infections.

Anticyclic citrullinated antibodies have a slightly lower sensitivity to the RF, being found in 57% (range, 12%-93%) of patients with RA, but ACPAs are more specific (96%) and may be detectable early in the disease.[40] The presence of ACPA, in general, predicts a more aggressive course of disease and increased risk of joint erosions. In contrast to RF, ACPAs are not typically present in patients with hepatitis C. Many rheumatologists order both tests in evaluating new patients.

Antinuclear antibodies (ANAs) are detected in 25% of patients with RA as a result of their disease. The presence of a positive ANA in a work-up of polyarthritis may initially lead to a diagnostic challenge, since they are more commonly seen in systemic lupus erythematosus, systemic sclerosis, and mixed connective tissue disease, all of which can have arthritis as a presenting feature. However, patients with RA who have a positive ANA would not be expected to be positive for more specific antibodies for connective tissue disorders, including anti-ds DNA antibodies, anti-Smith antibodies, anti-SCL 70 antibodies, or anti-RNP antibodies.

Synovial fluid analysis may be performed during the initial diagnosis or follow-up in patients with RA to rule out crystalline disease or infection in swollen joints (especially joints that are swollen out of proportion to the rest of the clinical examination). Synovial fluid analysis of involved joints typically reveals white blood cell counts of 1,500 to 25,000/mm^3 (1.5×10^9 to 25×10^9/L) but may be higher in those with active RA.[41]

Plain radiographs in RA are often normal at the time of disease presentation. The earliest plain radiographic findings typically include soft tissue swelling and periarticular osteoporosis on hand and foot x-rays. As RA progresses, joint space narrowing occurs as a result of cartilage degradation, and marginal erosions (at the margins of the joint capsules) may occur, typically in the ulnar styloid, metacarpophalangeal and proximal interphalangeal joints of the hands (Fig. 111-5), and the metatarsophalangeal joints of the feet. In advanced stages of RA, radiographs may show deformities including joint subluxations, ulnar deviation of the metacarpophalangeal joints, and secondary osteoarthritis. Many DMARD and biologic therapies halt the progression of erosive changes in RA. Serial joint radiographs may be used in addition to clinical findings as a way of evaluating disease progression and adequacy of therapy.

DIAGNOSTIC CRITERIA

In 2010, the American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) updated their classification criteria for RA.[42] The revised criteria allow for identification of patients at an earlier stage of disease, such as synovitis of one small joint in the absence of an alternative diagnosis. Early identification of patients with RA may allow for earlier treatment geared toward preventing structural damage to joints.

The criteria use a scoring system which assigns points based upon the number and types (small and large) of joints involved. The presence of RF or ACPA and elevated acute phase reactants (CRP and ESR) result in additional points. A duration of symptoms of 6 weeks or more provides an additional point. A total score of 6 or more out of a possible total score of 10 is considered diagnostic for RA (Table 111-1).[42] Not all patients with RA will score 6 or greater initially but may evolve to higher scores over time.

TABLE 111-1

ACR/EULAR Rheumatoid Arthritis Classification Criteria

Criteria	Score
Low-positive RF or ACPA	2
High-positive RF or ACPA	3
High ESR or CRP	1
Duration of symptoms ≥6 weeks	1
Joint Involvement (at least one joint not explained by another disease)	
2-10 large joints	1
1-3 small joints (± large joint)	2
4-10 small joints (± large joint)	3
>10 joints (at least one small joint)	5

ACR/EULAR, American College of Rheumatology/European League Against Rheumatism; ACPA, anticitrullinated protein antibodies; CRP, C-reactive protein; ESR, eosinophil sedimentation rate; RF, rheumatoid factor.

Patients with inflammatory arthritis who have negative RF and ACPA may be diagnosed with RA if they fulfill further criteria otherwise characteristic of RA. In addition, a number of other inflammatory arthritic conditions are managed similarly to seropositive rheumatoid arthritis; these include psoriatic arthritis, reactive arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease.

TREATMENT

Desired Outcomes

The ACR as well as the EULAR guidelines recommend a treat-to-target approach when treating patients with RA rather than a nontargeted treatment approach. If remission cannot be achieved, low disease activity is an acceptable alternative target. This treatment approach is supported by superior clinical outcomes compared with usual care. In general, RA treatment is directed toward reducing inflammation and symptoms, including joint pain and stiffness. Most of the therapies used to treat RA slow the disease progression and thus the progression of irreversible joint damage, which can help decrease disability and improve quality of life.[43]

General Approach To Treatment

③ ④ Available pharmacologic therapies do not reverse joint damage that has already occurred. Therefore, early aggressive treatment of RA is imperative. Early treatment of RA results in improved outcomes. Patients with a shorter disease duration are more likely to respond to treatment.[44,45] Nonpharmacologic therapies also play a role in the management of RA and encourage patients to take an active role in managing their disease.[46] Therefore, the approach to the treatment of RA should include both pharmacologic and nonpharmacologic methodologies. Ultimately, care should be coordinated by a healthcare provider trained in rheumatology.

Nonpharmacologic Treatment

⑤ Nonpharmacologic approaches for the treatment of RA include referrals to occupational and physical therapy, mental health, social work, reviewing pain coping skills, and providing patient education. Both mental and physical health are important in patients with RA, as central neuroendocrine and dopaminergic pathways may be involved in both RA disease activity and physical and mental health. Patients with RA are also more likely to be affected by mood disorders and may benefit from referrals to specialty providers as appropriate.[47]

Patient education should involve disease state education as well as medication education related to potential adverse effects and how to appropriately administer injectable agents. Physical therapy is beneficial for reducing pain and inflammation while preserving joint function. The benefits of exercise and physical activity, including aerobic activity and muscle-strengthening exercises, have been demonstrated to improve RA-related disease outcomes. Assistive devices and orthoses such as braces and supports are useful to improve pain and function. Occupational therapy can be effective and provide several benefits such as exercises, appropriate footwear, and splinting.[46] Weight loss can help decrease the stress on joints. Surgical options, including joint replacements, are reserved for patients with more severe disease where there may have significant cartilage loss.

Pharmacologic Therapy

Currently available therapies used to treat RA and also slow the progression of the disease include conventional and biologic DMARDs and the small-molecule agents tofacitinib, baricitinib, and upadacitinib. Conventional DMARDs include methotrexate, leflunomide, sulfasalazine, and hydroxychloroquine. Biologic DMARDs fall into two categories: tissue necrosis factor (TNF) inhibitor biologics (adalimumab, etanercept, certolizumab, golimumab, and infliximab) and non-TNF biologics (abatacept, tocilizumab, rituximab, anakinra, and sarilumab). Tofacitinib, baricitinib, and upadacitinib are oral synthetic DMARDs that are also Janus Kinase (JAK) inhibitors. Many of the therapies used to treat RA are also indicated and used in the treatment of other conditions such as psoriatic arthritis and ankylosing spondylitis, conditions that are outside the scope of this chapter. Table 111-2 includes RA-indicated dosages for the agents discussed in this chapter.

TABLE 111-2

Usual Doses for Disease-Modifying Antirheumatic Drugs

Drugs	Brand Names	Routes of Administration	Starting Doses	Usual Ranges or Maintenance Doses	Comments
Methotrexate	• Rasuvo • Trexall • Otrexup (SubQ)	Oral, SubQ, IM	• Oral: 7.5 mg once weekly or 2.5 mg every 12 hours for 3 doses once weekly • SubQ/IM: 7.5 mg once weekly	7.5-20 mg once weekly	May be given with folic acid 1-5 mg/day to reduce adverse reactions
Leflunomide	Arava	Oral	Loading dose: 100 mg daily for 3 days, then 20 mg daily or 10-20 mg daily without loading	10-20 mg daily	Not recommended in liver disease (ALT >3 times ULN)

			dose		
Hydroxychloroquine	Plaquenil	Oral	200 mg twice daily or 400 mg daily	200 mg twice daily or 400 mg daily	Take with food or milk; use with caution in renal or hepatic impairment
Sulfasalazine	Azulfidine	Oral	500 mg once or twice daily	1,000 mg twice daily (maximum dose is 3,000 mg/day if inadequate response after 12 weeks of 2,000 mg/day)	Not recommended in renal or hepatic impairment
Etanercept	Enbrel	SubQ	50 mg once weekly or 25 mg twice weekly	Same as starting dose	
Infliximab	Remicade	IV	3 mg/kg at 0, 2, 6 weeks, and then every 8 weeks	3-10 mg/kg every 4-8 weeks	Given in combination with methotrexate therapy; pretreat with methylprednisolone, acetaminophen, and antihistamine
Adalimumab	Humira	SubQ	40 mg every 2 weeks	40 mg every 2 weeks (may increase to 40 mg once weekly if not taking methotrexate)	
Certolizumab	Cimzia	SubQ	400 mg at 0, 2, 4 weeks	200 mg every other week or 400 mg every 4 weeks	
Golimumab	Simponi	SubQ	50 mg once monthly	Same as starting dose	
Rituximab	Rituxan	IV	1,000 mg in 2 doses given 2 weeks apart	Initial dose may be repeated every 16-24 weeks based on response	Pretreat with methylprednisolone, acetaminophen, and antihistamine
Abatacept	Orencia	IV, SubQ	• IV: <60 kg: 500 mg, 60-100 kg: 750 mg, >100 kg: 1,000 mg at 0, 2, and 4 weeks or initial IV dose followed by 125 mg subcutaneously within 24 hours • SubQ: 125 mg weekly	• IV: dose based on weight every 4 weeks • SubQ: 125 mg weekly	
Tocilizumab	Actemra	IV, SubQ	IV: 4 mg/kg every 4 weeks SubQ: <100 kg:	• IV: 4-8 mg/kg every 4 weeks	Can increase the metabolism of CYP3A4 substrates

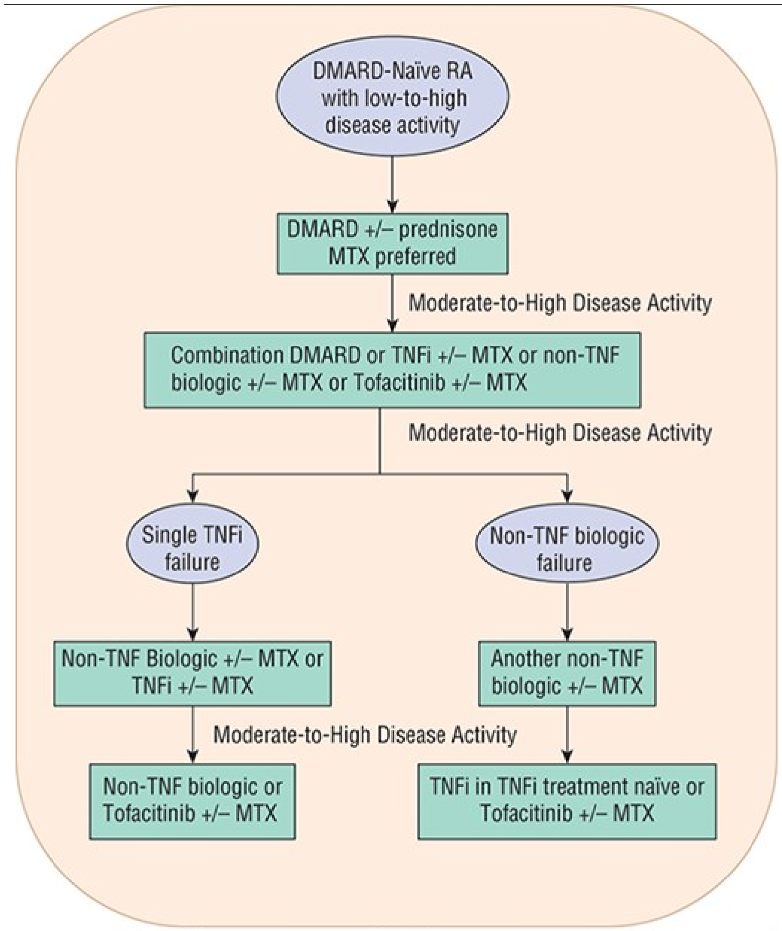
			162 mg every other week, >100 kg 162 mg weekly	(maximum 800 mg per infusion) - Subcutaneously: <100 kg: 162 mg every other week, followed by an increase to weekly injections if needed, >100 kg: 162 mg weekly	
Tofacitinib	Xeljanz	Oral	- IR: 5 mg twice daily - ER: 11 mg daily	Same as starting dose	5 mg once daily in moderate-to-severe renal insufficiency, moderate hepatic impairment, or concomitant CYP3A4 or CYP2C19 inhibitors
Upadacitinib	Rinvoq	Oral	ER: 15 mg daily	Same as starting dose	Use is not recommended in severe hepatic impairment.
Baricitinib	Olumiant	Oral	2 mg daily	Same as starting dose	eGFR 30-60 mL/min/1.73 m^2: 1 mg daily; Use is not recommended with eGFR <30 mL/min/1.73 m^2; Use is not recommended in severe hepatic impairment; Dosage adjustment for concomitant strong organic anion transporter 3: 1 mg daily.
Anakinra	Kineret	SubQ	100 mg once daily	Same as starting dose	
Sarilumab	Kevzara	SubQ	200 mg every 2 weeks	Same as starting dose	

ALT, alanine transaminase; CYP, cytochrome P; ER, extended release; IR, immediate release; ULN, upper limit of normal; IM, intramuscular; SubQ, subcutaneous; IV, intravenous.

⑥ ⑦ The current ACR guidelines for treatment of RA recommend initiation of conventional DMARDs irrespective of disease activity in treatment-naive patients (Fig. 111-6) once a diagnosis is established. The preferred conventional DMARD is methotrexate unless a contraindication to its use exists.[48,49] In practice, choice of therapy may ultimately be dependent on level of disease activity, comorbid health conditions, patient preference, and often insurance coverage.

FIGURE 111-6

Treatment algorithm for rheumatoid arthritis based on the American College of Rheumatology guidelines. (DMARD, disease-modifying antirheumatic drug; MTX, methotrexate; TNF, tumor necrosis factor) *(Data from Reference 50.)*



DMARD-Naïve RA with low-to-high disease activity
DMARD +/– prednisone MTX preferred
Moderate-to-High Disease Activity
Combination DMARD or TNFi +/– MTX or non-TNF biologic +/– MTX or Tofacitinib +/– MTX
Moderate-to-High Disease Activity
Single TNFi failure
Non-TNF biologic failure
Non-TNF Biologic +/– MTX or TNFi +/– MTX
Another non-TNF biologic +/– MTX
Moderate-to-High Disease Activity
Non-TNF biologic or Tofacitinib +/– MTX
TNFi in TNFi treatment naïve or Tofacitinib +/– MTX

The ACR guidelines recommend treatment with DMARD monotherapy for patients with early RA—defined as duration of disease/symptoms of less than 6 months—and low disease activity. Double or triple DMARD therapy is recommended if disease activity is moderate or high. A biologic agent can be used as monotherapy or with conventional DMARD(s) in patients with moderate or high disease activity. Tofacitinib would be an alternate option if disease activity remains moderate or high with combination conventional DMARDs. If disease activity remains moderate or high despite DMARD or biologic agents, a low-dose glucocorticoid can be added for the shortest duration of time necessary. Low-dose glucocorticoid is defined as prednisone 10 mg/day or less or an equivalent amount of another glucocorticoid. If patients achieve remission, DMARDs and biologic agents can be tapered; however, patients should remain on DMARD therapy at some level.

In patients with established RA—defined as duration of disease/symptoms for 6 months or more—treatment with DMARD monotherapy is recommended despite disease activity in DMARD-naive patients. Combination conventional DMARDs or a biologic DMARD or tofacitinib can be used if disease activity remains moderate or high after an adequate trial with DMARD monotherapy. In patients who are on TNF inhibitor monotherapy with moderate or high disease activity, one or two DMARDs can be added to the TNF inhibitor. A non-TNF biologic can be used in place of a TNF inhibitor if disease activity remains moderate or high on a TNF inhibitor. This is recommended over tofacitinib. Therapy can be switched to another non-TNF biologic if a single non-TNF biologic is unable to adequately control disease activity. If courses of two TNF inhibitors have not adequately controlled disease activity, a non-TNF biologic can be initiated. Tofacitinib can be initiated if disease activity persists despite multiple TNF inhibitors in patients for whom non-TNF biologics are not an option. Glucocorticoids can be added if disease flares occur or are inadequately controlled despite DMARD, TNF inhibitor, or non-TNF biologic therapy.[41] It is worth mentioning that the newer JAK inhibitors, baricitinib and upadacitinib, were not yet approved at the time of these ACR guidelines and, therefore, only tofacitinib is listed specifically.

In contrast to the ACR guidelines, the 2019 EULAR guidelines delineates treatment recommendations based on past therapy, clinical response, and presence of poor prognostic factors (Fig. 111-7). Poor prognostic factors are defined as high disease activity, early joint damage, positive RF or ACPA, and failure of >2 conventional DMARDs. Dosages and therapies should be reassessed no later than 3 months after the initiation or change. The algorithm also provides dose reduction recommendations for persistent disease remission of at least 6 months in duration, especially if having tapered glucocorticoid therapy. It is not recommended that all pharmacologic treatment be completely discontinued.[50]

⑧ DMARDs can take weeks to months to take effect in patients with RA. NSAIDs and/or glucocorticoids, as well as other analgesics such as acetaminophen, can provide symptomatic relief and have a more rapid onset of action than DMARDs; they are often used as “bridge” therapy. NSAIDs do not impact disease progression, and corticosteroids have several side effects associated with their use, making both less desirable choices for long-term use.

Conventional Disease-Modifying Antirheumatic Drugs

Methotrexate

Methotrexate is the DMARD of choice for most patients unless its use is contraindicated. Methotrexate has been used in the treatment of RA for several decades and has a sustained clinical response over time and a glucocorticoid-sparing effect.[51] It can be taken as monotherapy or in combination with other DMARDs.

Methotrexate is a structural analogue of folic acid that inhibits dihydrofolate reductase. Dihydrofolate reductase is the enzyme responsible for reducing dihydrofolic acid to folinic acid, the active intracellular metabolite. Through this action, methotrexate inhibits DNA synthesis and repair and cellular replication.[52]

Methotrexate is taken once weekly and is typically given in either tablet form or as a subcutaneous injection. It is also available as an intramuscular injection. The absorption of oral methotrexate is highly variable. At low doses (≤30 mg/m^2), oral bioavailability is about 60%, and this decreases at higher doses. Methotrexate is about 50% protein bound and is excreted by the kidney, about 80% to 90% unchanged.[52] Injectable methotrexate has a higher bioavailability compared with oral methotrexate and thus provides superior clinical efficacy. Injectable methotrexate is typically better tolerated and has less potential to cause gastrointestinal side effects as well.[53] The doses used for the treatment of RA typically range from 7.5 to 20 mg weekly. Doses exceeding 20 mg weekly can increase the risk for toxicities.[52] At doses higher than 15 mg weekly, oral methotrexate may not have significant added clinical benefit; changing to subcutaneous methotrexate may increase bioavailability and clinical benefit.[8] Clinical benefit can be seen 3 to 6 weeks after starting methotrexate therapy.[52]

Methotrexate is teratogenic and is therefore contraindicated in pregnancy and breastfeeding. Additional contraindications include alcoholism, alcoholic liver disease or other chronic liver disease, immunodeficiency, and preexisting hematologic disorders, such as leukopenia and thrombocytopenia. Methotrexate excretion is reduced in renal impairment and may require dose reduction or discontinuation in some cases. Excretion is also reduced in ascites or pleural effusions.[52]

Recommended laboratory monitoring prior to starting methotrexate includes a complete blood count (CBC) with differential, alanine transaminase (ALT), aspartate transaminase (AST), and renal function. These should be monitored every 2 to 4 weeks for 3 months after initiation or following a dose increase, then every 8 to 12 weeks during 3 to 6 months of therapy, and every 12 weeks after 6 months of therapy.[5] A chest x-ray film can be considered before starting methotrexate in patients with underlying lung disease. Hepatitis B, hepatitis C, and tuberculosis screenings should be obtained at baseline in high-risk patients.[54]

Adverse effects of methotrexate include infection, pulmonary complications (eg, interstitial pneumonitis and chronic obstructive pulmonary disease [COPD]), gastrointestinal problems (eg, perforation and diarrhea), hematologic changes (eg, thrombocytopenia and leukopenia), and hepatic toxicities (eg, elevated liver enzymes and cirrhosis). Because methotrexate is a structural analogue of folic acid, it can cause folic acid deficiency; methotrexate should be given with folic acid 1 to 5 mg daily to reduce the incidence of toxicities associated with methotrexate.[52]

Leflunomide

Leflunomide, an oral DMARD that inhibits pyrimidine synthesis, can be used as monotherapy or in combination with other DMARDs to treat RA. Leflunomide reduces signs and symptoms of RA, inhibits structural damage, and improves physical function. It is significantly protein bound (>99.3%). The typical maintenance dose used to treat RA is 20 mg daily; the dose can be decreased to 10 mg daily if patients are unable to tolerate higher doses. A loading dose can be given of 100 mg for 3 days to achieve steady state more rapidly, but this may increase the risk for toxicities.

Leflunomide has a half-life of about 2 weeks and may require washout with cholestyramine if rapid elimination is required due to toxicity or incidental pregnancy. Leflunomide is excreted by the kidneys as well as through direct biliary excretion.[9] Baseline monitoring should include a tuberculosis screening, CBC with differential, ALT, AST, and renal function. These should be monitored every 2 to 4 weeks for 3 months after initiation or following a dose increase, then every 8 to 12 weeks during 3 to 6 months of therapy, and every 12 weeks after 6 months of therapy.

Adverse reactions associated with leflunomide include diarrhea, elevated liver enzymes, alopecia, elevated blood pressure, and rash. If ALT is three times the upper limit of normal (ULN), leflunomide should be discontinued. Leflunomide should not be used in pregnant or nursing mothers or in patients with severe hepatic impairment.[55]

Sulfasalazine

Sulfasalazine is a prodrug with two metabolites, 5-aminosalicylic acid (5-ASA) and sulfapyridine. The exact mechanism of action of sulfasalazine for the treatment of RA is unknown; however, it has immunomodulating and anti-inflammatory properties. Sulfasalazine can be used as monotherapy or in combination with other DMARDs to treat RA. The typical starting dose of sulfasalazine is 500 mg daily or 1 g daily in two divided doses; this can be increased weekly to 2 g daily in two divided doses to minimize the risk of adverse events. Clinical benefit can be seen in 4 weeks, but some individuals may need to be on sulfasalazine for 12 weeks before clinical benefit is achieved. If clinical benefit is not sufficient after 12 weeks of therapy, the dose can be further titrated to 3 g/day in evenly divided doses.

Sulfasalazine is primarily eliminated by the kidney and should be used with caution in renal impairment. Sulfasalazine is contraindicated in sulfonamide or salicylate allergy.[56] Baseline monitoring should include a CBC with differential, ALT, AST, and renal function.[56] These should be monitored every 2 to 4 weeks for 3 months after initiation or following a dose increase, then every 8 to 12 weeks during 3 to 6 months of therapy, and every 12 weeks after 6 months of therapy. Glucose-6-phosphate dehydrogenase deficiency can cause hemolytic anemia; therefore, screening for this prior to initiation should be considered.[57]

Sulfasalazine use is limited by its potential to cause gastrointestinal adverse effects, including diarrhea, nausea, vomiting, and anorexia. Less common adverse effects associated with sulfasalazine include rash, urticaria, blood cell abnormalities (including leukopenia, anemia, and thrombocytopenia), severe hypersensitivity reactions (including Stevens-Johnson syndrome), photosensitivity, elevated liver enzymes, and alopecia. Sulfasalazine can also cause urine and skin discoloration. Sulfasalazine crosses the placenta and is present in breast milk but can be used in pregnant and nursing mothers with caution.[56]

Hydroxychloroquine

Hydroxychloroquine is typically used in combination with other DMARDs in patients with RA, but it can be used as monotherapy in mild cases. The mechanism of action in the treatment of RA is not fully understood, but a proposed mechanism for its anti-inflammatory properties is its interference with antigen processing in macrophages and other antigen-presenting cells.[57] Hydroxychloroquine's oral absorption is incomplete and inconsistent, varying from 25% to 100%. It is about 40% protein bound and excreted predominately in the urine.[58]

The typical dose of hydroxychloroquine is 400 mg daily either as one dose or as two divided doses. Clinical benefit is delayed and may take several weeks. The main advantage of hydroxychloroquine use is that it does not require frequent, routine laboratory monitoring because it is not generally associated with infection risk or hepatic, renal, or blood cell abnormalities. The most common adverse effects with hydroxychloroquine are gastrointestinal side effects, including nausea, vomiting, and diarrhea; these can sometimes be mitigated by taking the medication with food or splitting the dose into two doses.[46]

Irreversible retinal damage can occur with hydroxychloroquine use. For patients with risk factors for developing retinal damage, such as low body weight and renal and hepatic impairment, ophthalmologic exams should be conducted annually throughout the treatment with this drug. If patients do not have risk factors for developing retinal damage, an ophthalmologic examination should be completed within 5 years of starting hydroxychloroquine and then repeated annually.[46,59]

Hydroxychloroquine can be continued during pregnancy as there is no increased risk of birth defects or ocular toxicities. Hydroxychloroquine is excreted into the breast milk, and caution should be exercised in nursing mothers.[60]

Biologic Disease-Modifying Antirheumatic Drugs

Biologics agents are genetically engineered protein molecules that have varying mechanisms by which they decrease inflammation. They can be separated into two groups: TNF inhibitor biologics including adalimumab, etanercept, certolizumab, golimumab, and infliximab; and non-TNF biologics including abatacept, tocilizumab, rituximab, anakinra, and sarilumab.

Biologic DMARDs are associated with an increased risk of infection due to their immunosuppressant effects. A tuberculin skin test or interferon gamma release assay (IGRA) blood test should be obtained before starting a biologic to detect and treat latent or active tuberculosis. Patients should also be screened for hepatitis B before starting biologic therapy because of the risk for reactivation.

Biologic agents can be used in combination with conventional DMARDs, but multiple biologics should not be used concomitantly due to additive immunosuppressive effects. In general, if patients are switched from one biologic to another, the new agent should be initiated when the patient is due for a dose of the previous biologic to avoid potential adverse effects. Because of the immunosuppressive effects of these agents, patients should notify their providers if they are being treated for an infection or plan to undergo major surgery while on a biologic or before starting a biologic. A patient's therapy may need to be held until appropriate postsurgical healing and/or resolution of infection can be confirmed.

TNF Inhibitor Biologics

TNF inhibitors block the proinflammatory cytokine TNF-α. Elevated levels of TNF-α are found in the synovial fluid of individuals with RA as well as other rheumatologic conditions. Adalimumab, etanercept, golimumab, certolizumab, and infliximab can take several weeks for clinical benefit to be noted and up to 3 months to achieve full clinical benefit.[61] The place in therapy for these agents is typically when disease activity remains moderate or high despite conventional DMARD therapy.

A major limitation to the use of TNF inhibitors is cost, as they are more expensive than conventional DMARDs. To optimize the use of TNF inhibitors, medication education should include site of administration, expected time to benefit, safe storage, proper disposal, and possible side effects.

Although these agents have similar side effect profile and contraindications, the TNF inhibitors all have differing structures, pharmacokinetics, and dosing schemes. The selection of an agent depends on cost and patient preference for route and frequency of administration. TNF inhibitors should not be used in patients with moderate-to-severe heart failure (New York Heart Association [NYHA] class III/IV), as new-onset and worsening heart failure has been reported with TNF inhibitors. These agents increase the risk of serious infection and malignancies such as lymphoma and skin cancers.

New-onset or exacerbation of demyelinating disorders such as multiple sclerosis has been observed with TNF-α inhibitors. Therapy should be discontinued in patients who develop symptoms of demyelinating disorders, and caution should be exercised in using these agents in this patient population. Before starting TNF inhibitors, patients should be screened for tuberculosis and hepatitis B. During therapy, a CBC with differential should be monitored periodically as TNF inhibitors can cause blood cell disorders including pancytopenia. Other monitoring includes signs/symptoms of malignancy and serious infections.[61]

Certolizumab

Certolizumab is a pegylated humanized antibody Fab fragment of TNF-α monoclonal antibody. Because it is not a complete antibody and lacks the Fc region, it does not induce complement activation, antibody-dependent cell-mediated cytotoxicity, or apoptosis. Pegylation allows for delayed elimination and extended half-life. It is available as a prefilled syringe for subcutaneous injection. A loading dose of 400 mg at week 0, 2, and 4 can be given followed by a maintenance dose of 200 mg every other week or 400 mg every 4 weeks.

The most common adverse effects associated with certolizumab are upper respiratory tract infection, rash, and urinary tract infection. The safety and efficacy of certolizumab were evaluated in multiple studies that found that adult patients with moderate-to-severe RA treated with certolizumab had improved clinical response compared with placebo. Structural damage and RA progression was inhibited by certolizumab as compared with placebo plus methotrexate. Patients had improved function when treated with certolizumab compared with placebo.[62]

Adalimumab

Adalimumab binds to TNF-α and blocks its interaction with the p55 and p75 cell surface TNF receptors. It is available as a prefilled syringe or pen for subcutaneous injection. Typical dosing for RA is 40 mg every 2 weeks when used with methotrexate. The dose can be increased to 40 mg weekly if it is not being used with methotrexate. Local injection site reactions are the most common adverse event and usually manifest as redness, itching, pain, and swelling.

Adalimumab has been studied as monotherapy, with methotrexate, or as combination therapy with other DMARDs in patients with RA. It improves clinical response, delays the progression of structural damage, and improves function.[61]

Etanercept

Etanercept is a recombinant DNA-derived protein composed of TNF receptor linked to the Fc fragment of human IgG1. It is available as a prefilled syringe or pen for subcutaneous injection. Typical dosing for RA is 50 mg once weekly.[63]

The most common adverse effects associated with etanercept use include infections and injection site reactions. Patients treated with etanercept monotherapy and etanercept with methotrexate have improved clinical response. Clinical response was noted within 1 to 2 weeks of starting etanercept, but some patients required 3 months of therapy to demonstrate clinical response. Etanercept plus methotrexate decreased structural damage and progression of RA compared with monotherapy with etanercept or methotrexate. Function was also improved in patients treated with etanercept as compared with placebo.[63]

Golimumab

Golimumab is a human monoclonal antibody that binds to human TNF-α. It is available as a prefilled syringe or pen for subcutaneous injection and is typically dosed at 50 mg once monthly. It is also available as an intravenous product that dosed 2 mg/kg at weeks 0 and 4, and then every 8 weeks thereafter.

The most common adverse effects associated with golimumab use are upper respiratory tract infections and nasopharyngitis. Compared with methotrexate monotherapy, golimumab plus methotrexate improves clinical response in patients with RA. Golimumab also improves function in patients as compared with placebo.[64]

Infliximab

Infliximab is a chimeric monoclonal antibody that binds to human TNF-α. Infliximab is administered as an IV infusion and typical dosing is 3 mg/kg at weeks 0, 2, and 6, followed by every 8 weeks.

The most common adverse effects associated with infliximab use are infections, infusion-related reactions, headache, and abdominal pain.[41] About 15% of patients develop antibodies to infliximab. Patients who develop these antibodies typically have a higher likelihood of developing an infusion reaction, have increased clearance of infliximab, and therefore decreased efficacy. An electrochemiluminescence immunoassay (ECLIA) can be used to measure infliximab antibodies if this is suspected. When infusion reactions occur with infliximab, they typically begin within 2 hours of infusion. Concomitant use with immunosuppressants such as methotrexate can lessen the likelihood of developing antibodies to infliximab. Premedication with an antihistamine, acetaminophen, and/or a glucocorticoid can help decrease the likelihood of patients developing infusion-related reactions. Patients on infliximab plus methotrexate have an improved clinical response as compared with patients on methotrexate alone. Structural damage and progression of RA was also delayed.[65]

Non-TNF Biologics

Abatacept

Abatacept is a selective co-stimulation modulator that inhibits T-cell activation by binding to CD80 and CD86. This binding blocks the interaction between T cells CD28, thus inhibiting the activation of T cells. Activated T cells are found in the synovial fluid of patients with rheumatologic conditions such as RA and are thought to play a role in the disease. Abatacept is indicated for moderate-to-severe RA and can be used as monotherapy or in conjunction with conventional DMARDs.[66]

Abatacept is typically initiated if disease activity persists in patients after conventional DMARD monotherapy and can be an alternative to TNF inhibitors with or without methotrexate. It can also be initiated in patients who have failed or have had an inadequate response to TNF inhibitors. Abatacept plus methotrexate has similar efficacy and incidence of adverse events as compared with adalimumab plus methotrexate in biologic-naive patients who had an incomplete response to methotrexate.[67]

Abatacept is available in a prefilled syringe or autoinjector for subcutaneous injection and is given at a dose of 125 mg once weekly. It is also available as a 30-minute IV infusion that is dosed according to body weight (<60 kg: 500 mg; 60-100 kg: 750 mg; >100 kg: 1,000 mg); it is given at 0, 2, and 4 weeks and every 4 weeks thereafter.[66]

The most common side effects associated with abatacept include headache, upper respiratory tract infection, nasopharyngitis, and nausea. Abatacept should be used with caution in patients with COPD; exacerbations have been observed in patients with both COPD and RA on abatacept. Like other biologics, abatacept has also been associated with serious infections and malignancy. Infusion reactions are rare but can include anaphylaxis, hypotension, dyspnea, and urticaria and can occur within 24 hours of intravenous administration.[66]

Tocilizumab

Tocilizumab is a monoclonal antibody that inhibits the binding of the proinflammatory cytokine IL-6 to its receptor. Tocilizumab can be used in patients with moderate-to-severe RA who have had an incomplete response to one or more conventional DMARDs and/or TNF inhibitor and can be used as monotherapy or in combination with DMARDs.[68] A study that included patients with severe RA who could not use methotrexate found that tocilizumab monotherapy was more effective in the symptom management of RA compared to adalimumab monotherapy.[69]

Tocilizumab is available as a prefilled syringe for subcutaneous injection with dosing dependent on weight (<100 kg: 162 mg every other week, followed by an increase to weekly injections if needed based on clinical response; >100 kg: 162 mg weekly). It is also available as a 1-hour intravenous infusion at a dose of 4 mg/kg every 4 weeks; the dose can be increased to 8 mg/kg every 4 weeks if needed based on clinical response.[68]

The most common side effects associated with tocilizumab include upper respiratory tract infections, nasopharyngitis, headache, hypertension, increased liver enzymes, and injection site reactions. Infusion reactions can also occur, typically within 24 hours of infusion; these are manifest as headache, rash, pruritus, and urticaria. Tocilizumab can also cause gastrointestinal perforation, neutropenia, and thrombocytopenia as well as serious infections and malignancy. Baseline monitoring recommended should include neutrophils, platelets, lipid panel, AST, and ALT. Neutrophils, platelets, and liver enzymes should also be monitored 4 to 8 weeks after starting therapy and every 3 months thereafter. A lipid panel should be repeated after 4 to 8 weeks of treatment and every 6 months during treatment.[68]

Tocilizumab should not be initiated in patients with an absolute neutrophil count (ANC) of less than 2,000/mm^3 (2 × 10^9/L) or platelet count less than 100,000/mm^3 (100 × 10^9/L); treatment should be discontinued if ANC is less than 500/mm^3 (0.5 × 10^9/L) or platelet count is less than 50,000/mm^3 (50 × 10^9/L). Treatment should not be initiated if liver enzymes are greater than 1.5 times ULN and should be discontinued if liver enzymes are greater than five times ULN. Tocilizumab has the potential to increase the metabolism of drugs that are CYP450 substrates, particularly CYP3A4.[68]

Rituximab

Rituximab is a monoclonal antibody that binds the CD20 antigen found on the surface of B cells. Rituximab can be given as monotherapy or in combination with methotrexate and can be initiated in patients with moderate-to-severe RA who have had an incomplete response to one or more TNF inhibitors.[70] Patients who failed one TNF inhibitor had greater reductions in disease activity scores when treated with rituximab than with a second TNF inhibitor.[71]

Rituximab is available as an intravenous infusion and can be given as two 1,000-mg infusions separated by 2 weeks. The recovery of B-cells can take several months; therefore, rituximab can be given every 24 weeks. Some patients may not need to receive another dose as often as every 24 weeks; the decision to re-dose should be based on the return of RA symptoms. Rituximab should not be given more frequently than every 16 weeks.[70]

Methylprednisolone 100 mg administered intravenously is recommended 30 minutes before each infusion as well as acetaminophen and an antihistamine to reduce the development and severity of infusion reactions. Side effects that could occur with rituximab treatment include upper respiratory tract infection, nasopharyngitis, urinary tract infection, serious infections, bronchitis, infusion reactions, bowel obstruction/perforation, blood cell disorders, and cardiovascular events.[70] A CBC with differential should be obtained before treatment, with each infusion, and every 2 to 4 months.

Anakinra

Anakinra inhibits IL-1, which is involved in inflammatory responses. It can be used in patients with moderate-to-severe RA who have failed one or more DMARDs; however, the ACR did not include this drug in its 2015 RA treatment recommendations due to its infrequent use for the treatment of RA and lack of new data to support its use since 2012. It is a once-daily subcutaneous injection dosed at 100 mg.[72]

Sarilumab

Sarilumab is an IL-6 receptor antagonist that is indicated in the treatment of patients with moderate-to-severe RA who have had an incomplete response to one or more DMARDs. The ACR did not include this drug in their RA treatment recommendations because it had been approved when the 2015 recommendations were issued. Sarilumab can be used as monotherapy or with conventional DMARDs. It is a subcutaneous injection of 200 mg administered every 2 weeks.[73]

The most common adverse effects with sarilumab include neutropenia, increased liver enzymes, injection site reactions, and upper respiratory and urinary tract infections. It can also be associated with gastrointestinal perforation and serious infections. Monitoring of this medication should include a baseline tuberculosis screening, CBC with differential, and liver enzymes at baseline, 4 to 8 weeks later, and every 3 months thereafter, and a lipid panel at baseline, 4 to 8 weeks after starting therapy, and then every 6 months. Sarilumab should not be initiated in patients with ANC less than 2,000/mm^3 (2 × 10^9/L), platelets less than 150,000/mm^3 (150 × 10^9/L), or liver enzymes greater than 1.5 times ULN.[73]

The MOBILITY study included patients treated with sarilumab plus methotrexate compared with methotrexate plus placebo; sarilumab plus methotrexate produced a decrease in symptoms, improvement in function, and less progression of RA compared with placebo plus methotrexate.[74] In the TARGET study, sarilumab plus a DMARD reduced the symptoms of RA and improved function compared with placebo plus DMARD.[75]

Target-Specific DMARDs

Janus Kinase (JAK) Inhibitors

Tofacitinib and upadacitinib are oral (JAK) inhibitors approved for the treatment of moderate-to-severe rheumatoid arthritis with an inadequate response or intolerance to methotrexate. Baricitinib is a JAK inhibitor approved for the treatment of moderate-to-severe RA with an inadequate response to one or more TNFi therapies. Janus kinases function intracellularly in cell signaling for cytokine-activated receptors. JAK inhibitors bind to and modulate the catalytic activity of JAKs, thus blocking the messaging pathway of multiple pro-inflammatory cytokines and thereby exerting anti-inflammatory effects.[76,77]

JAK inhibitors can be used as monotherapy or in combination with conventional DMARDs and should not be used in combination with biologic DMARDs or other JAK inhibitors. These medications have black box warnings for serious infections including fungal, bacterial, and viral infections; malignancies, including lymphoma; and thrombosis, pulmonary embolism (PE), and deep vein thrombosis (DVT).[76,78,79]

Tofacitinib

Tofacitinib is available as a 5-mg immediate-release tablet and an 11-mg extended-release tablet. The recommended dosing is either 5 mg twice daily or 11 mg daily unless a dose reduction is recommended due to hepatic or renal impairment or if used concomitantly with CYP3A4 or CYP2C19 inhibitors.[76,78]

A common measure in studies of RA is *ACR 20* improvement, which is defined as at least a 20% improvement in seven ACR core measures of disease activity, including tender and swollen joints as well as patients' assessment of disease activity and physical function. It has been widely used to measure disease activity and response to therapy in clinical trials. Patients receiving tofacitinib with methotrexate had similar ACR 20 response after 6 months compared with adalimumab with methotrexate and a higher ACR 20 response compared to placebo with methotrexate.[80,81]

Adverse effects that can occur with tofacitinib include upper respiratory tract infection, cardiovascular effects, gastrointestinal perforation, serious infections, ILD, malignancy, nasopharyngitis, diarrhea, and headache. Because tofacitinib can be associated with bone marrow suppression, it should not be initiated when lymphocytes are less than 500 cells/mm^3 (0.5 × 10^9/L) or when ANC is less than 1,000 cells/mm^3 (1 × 10^9/L). Use should be avoided when hemoglobin is less than 9 g/dL (90 g/L; 5.59 mmol/L), and therapy should be interrupted if hemoglobin is less than 8 g/dL (80 g/L; 4.97 mmol/L) or decreases more than 2 g/dL (20 g/L; 1.24 mmol/L). Lymphocyte count should be monitored at baseline and every 3 months thereafter. ANA, platelet counts, and hemoglobin should be monitored at baseline, after 4 to 8 weeks of therapy, and every 3 months thereafter. Tofacitinib can also cause hyperlipidemia; lipids should be monitored 4 to 8 weeks after starting therapy and periodically thereafter. Hepatotoxicity can occur with treatment, and liver function test monitoring is recommended. Use in severe hepatic impairment is not recommended.[76]

An ongoing, open-label study evaluating the safety of tofacitinib 5 mg twice daily and 10 mg twice daily showed that patients with RA, who are 50 years or older with at least one cardiovascular risk factor, had a higher rate of all-cause mortality on tofacitinib 10 mg twice daily versus 5 mg twice daily on TNF inhibitors. These preliminary findings prompted a black box warning of mortality for tofacitinib. Of note, tofacitinib 10 mg twice daily is only FDA approved for the treatment of ulcerative colitis.[82]

Upadacitinib

Upadacitinib is available as a 15-mg extended-release 24-hour oral tablet dosed once daily. No renal dose adjustment is recommended; however, upadacitinib has not been studied in end-stage renal disease (eGFR <15 mL/min/1.73 m^2). It can be utilized in mild-to-moderate hepatic impairment, but use is not recommended in severe hepatic dysfunction. Caution should be exercised when using upadacitinib in patients on strong CYP3A4 inhibitors, and use with strong CYP3A4 inducers is not recommended. Upadacitinib should not be started in patients with absolute lymphocyte count (ALC) less than 500 cells/mm^3 (0.5 × 10^9/L), absolute neutrophil count (ANC) less than 1,000 cells/mm^3 (1 × 10^9/L), or hemoglobin less than 8 g/dL (80 g/L; 4.97 mmol/L).[79]

A phase III, double-blind, randomized controlled trial evaluating the efficacy and safety of upadacitinib compared to placebo or adalimumab in patients with RA and a history of inadequate response to methotrexate showed that upadacitinib was superior to placebo and adalimumab in improving signs, symptoms, and physical function in RA patients. Patients on upadacitinib had significantly less radiographic progression of RA compared to placebo. The safety profile of upadacitinib was similar to adalimumab, except for higher rates of herpes zoster and creatine phosphokinase (CPK) elevations in patients on upadacitinib.[83]

Adverse effects that may occur with upadacitinib include upper respiratory tract infections, neutropenia, lymphocytopenia, nausea, hepatotoxicity, CPK elevations, DVT, PE, increased cholesterol, and gastrointestinal perforation. Therapy should be interrupted if neutropenia, lymphopenia, or anemia occurs past the above ALC and ANC thresholds during treatment.

Recommended monitoring for upadacitinib includes lymphocyte count, ANC, hemoglobin, and liver function tests at baseline and periodically throughout treatment, lipids 12 weeks after initiation and periodically throughout treatment, hepatitis screenings prior to initiation and periodically thereafter, tuberculosis screening at baseline, signs and symptoms of infection during and after therapy, periodic skin examinations, and signs or symptoms of thrombosis throughout treatment.[79]

Baricitinib

Baricitinib is available as a 1-mg and 2-mg tablet and is typically dosed at 2 mg daily with eGFR greater than 60 mL/min/1.73 m^2. A dose reduction to 1 mg daily is recommended with eGFR 30 to 60 mL/min/1.73 m^2 and use is contraindicated with eGFR less than 30 mL/min/1.73 m^2. Use in severe hepatic impairment has not been studied and is therefore not recommended. A dose reduction to 1 mg daily is also recommended when used concomitantly with strong organic anion transporter 3 inhibitors, such as probenecid. Baricitinib should not be started in patients with ALC less than 500 cells/mm^3 (0.5×10^9/L), ANC less than 1,000 cells/mm^3 (1×10^9/L), or hemoglobin less than 8 g/dL (80 g/L; 4.97 mmol/L).[78]

A phase III, double-blind study comparing baricitinib to placebo in patients with RA and inadequate response or intolerance to one or more conventional DMARDs showed that patients on baricitinib had statistically significant improvements in signs and symptoms of RA, including morning stiffness and joint pain, and achieved an ACR20 response compared to placebo. Baricitinib also slowed radiographic progression of RA-related joint damage.[84]

Adverse effects that may occur with baricitinib use include upper respiratory tract infections, herpes zoster infection, hepatotoxicity, hematologic toxicities including anemia, gastrointestinal perforations, thrombosis, lymphocytopenia, neutropenia, increase in SCr and CPK. Therapy should be interrupted if neutropenia, lymphopenia, or anemia occurs past the above ALC and ANC thresholds during treatment.[84]

Recommended monitoring for baricitinib includes lymphocyte, ANC, platelet counts, hemoglobin, and LFTs at baseline and periodically throughout treatment, lipids 12 weeks after therapy and periodically throughout treatment, hepatitis B screening prior to starting therapy, signs and symptoms of infection, abdominal symptoms, and skin examinations periodically.[78]

Other Disease-Modifying Antirheumatic Drugs

Therapies such as azathioprine, cyclosporine, minocycline, and gold salts were previously used to treat RA. With the development of other DMARDs and biologics, they are now used infrequently and have no recent data to support their use.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs inhibit prostaglandin synthesis and can provide anti-inflammatory as well as analgesic effects. However, they do not slow disease progression and should not be used as monotherapy. NSAIDs can provide symptomatic relief from pain and stiffness and can be effective as adjuncts to DMARD therapy in patients with RA. They have a more rapid onset of action than DMARDs and may be beneficial to “bridge” patients while DMARDs take effect.

Although these agents are available without prescription, they still possess potentially serious risks to use. In the United States, NSAIDs carry a Boxed Warning because they increase the risk of serious cardiovascular thrombotic events, including myocardial infarction and stroke.[85] Their use is also associated with serious gastrointestinal bleeding and ulcerations. For more details on NSAIDs, see Chapter 110, “Osteoarthritis.”

Glucocorticoids

Glucocorticoids have been used in the treatment of RA for their anti-inflammatory and immune-modulating effects.[84] Although these agents slow the progression of RA, glucocorticoids should not be used as monotherapy in the treatment of RA, particularly due to the potential for serious, long-term adverse effects. Therefore, they should be used at the lowest effective dose for the shortest period of time. According to the ACR, short-term glucocorticoid is defined as less than 3 months of therapy and low-dose glucocorticoid is defined as prednisone 10 mg/day or less or its equivalent.

Glucocorticoids can be administered orally or intramuscularly. They act systemically to decrease inflammation and pain. Intra-articular injections administered directly into joints can provide a local decrease in inflammation and pain relief. The intra-articular route is associated with fewer systemic adverse effects because of the limited systemic action. Intra-articular injections should not be repeated more often than every 3 months because of the potential for accelerated loss of cartilage in the joint. Oral glucocorticoids are absorbed almost completely in the gastrointestinal tract, metabolized in the liver, and eliminated in the urine. Typically, oral glucocorticoids, such as prednisone, are taken once daily. Intramuscular glucocorticoids such as triamcinolone acetonide and methylprednisolone acetate can be administered instead of oral steroids based on patient preference or in patients who may not adhere to daily oral therapy. This can also be used in place of an intra-articular injection when multiple joints are involved. To avoid withdrawal associated with hypothalamus–pituitary–adrenal (HPA) axis suppression, glucocorticoids should not be stopped abruptly but should be tapered, especially when used for long term or at high doses. Intramuscular glucocorticoids provide patients with a physiologic taper.

Similar to NSAIDs, glucocorticoids can be used to “bridge” patients while DMARDs take effect. They can also be used as adjuncts to DMARDs at the lowest dose possible in patients with refractory disease. High-dose, short-term bursts can be used as needed for acute flares of RA symptoms, followed by tapering to the lowest effective dose to control symptoms or until discontinued over several days.[86]

Use of long-term glucocorticoids is limited by adverse effects, which include fluid retention, hyperglycemia, hypertension, behavioral and mood changes, increased appetite, weight gain, electrolyte imbalances, impaired healing, hirsutism, Cushing syndrome, HPA axis suppression, osteonecrosis of femoral and humeral heads, osteoporosis and fractures, myopathy, glaucoma, and cataracts.[87,88] The lowest effective dose for the shortest period of time should be used to minimize the potential for these adverse effects. Patients with RA are at a higher risk of developing osteoporosis, and the use of long-term glucocorticoids doubles this risk. In a study of prednisone 7.5 mg daily, patients lost an average of 9.5% of bone in the spine over 20 weeks of treatment.[88] For more information on glucocorticoid-induced bone loss, see Chapter 112, “Osteoporosis.”

Special Populations

Pregnancy and Lactation

Data on the safety of a majority of the medications used to treat RA during pregnancy and breastfeeding are limited, and a majority of medications with available safety data in this population have been associated with adverse effects. The potential risks of becoming pregnant should be discussed with women of childbearing age who are being treated for RA, and contraception counseling should be discussed for those not planning on becoming pregnant. Approximately 20% to 40% of patients with RA achieve remission during the third trimester of pregnancy and remission is more common in women with RF-negative RA.[89]

Because of risks associated with paternal exposure to DMARDs, family planning for male patients should also be taken into account when developing treatment plans.[89]

In women who want to become pregnant, therapies that are contraindicated in pregnancy such as methotrexate and leflunomide should be discontinued. Medications that are unsafe during pregnancy or have inadequate data to determine safety, such as abatacept, tocilizumab, rituximab, tofacitinib, and anakinra, should also be discontinued. Disease activity should then be monitored. For symptom control, NSAIDs, acetaminophen, and glucocorticoids can be considered. DMARDs that can be used during pregnancy include hydroxychloroquine and sulfasalazine.[89] Newer medications including upadacitinib, baricitinib, and sarilumab do not have sufficient data available to determine safety during pregnancy.[73,78,79]

There is no increase in congenital malformations with use of TNF inhibitors and therefore they may be considered for use during the first part of pregnancy.[89,90] Specifically, etanercept and certolizumab may be continued throughout pregnancy.[90]

For women who are breastfeeding, methotrexate and leflunomide are contraindicated. NSAIDs, acetaminophen, hydroxychloroquine, sulfasalazine, and glucocorticoids are preferred. TNF inhibitors, anakinra, abatacept, rituximab, tocilizumab, tofacitinib, sarilumab, baricitinib, and upadacitinib do not have sufficient evidence to recommend safe use during breastfeeding.[79,89] Since TNF inhibitors are large protein molecules, little to no drug is likely to be found in breastmilk.[90]

For male patients with RA, methotrexate should be held for 3 months before conception, and sulfasalazine may need to be held if the patient is having difficulty with fertility. There is limited data on adverse outcomes with leflunomide. TNF inhibitors can disrupt spermatogenesis, but use could be considered. Adverse outcomes have been reported with rituximab and abatacept.[89]

Serious Infections

In patients with a history of serious infections, combination DMARDs are recommended over TNF inhibitors. Abatacept can be considered over TNF inhibitors; in a study of patients hospitalized for an infection while on TNF inhibitors, abatacept was associated with the lowest risk of a subsequent infection compared with other biologics.[43]

In patients who screen positive for tuberculosis via either a tuberculin skin test or IGRA, a chest x-ray film should be obtained to determine if the patient has latent or active tuberculosis infection. If the chest x-ray film is positive, a sputum for acid-fast bacillus (AFB) can be collected to rule out active tuberculosis. If this is negative, then the patient likely has latent tuberculosis and a biologic DMARD or tofacitinib can be started or resumed after completing at least 1 month of treatment for latent tuberculosis. If the test is positive, then the patient likely has active tuberculosis and a biologic DMARD or tofacitinib can be started or resumed after the patient has completed treatment for active tuberculosis.[43]

Hepatitis

In patients with hepatitis B infection who are receiving treatment for hepatitis B, treatment of RA should be the same as in patients without a history of hepatitis. In patients with prior exposure to hepatitis B, RA treatment should be the same as unexposed patients, with monitoring of viral load every 6 to 12 months. In patients with history of untreated hepatitis B, treatment of hepatitis B should be considered prior to initiating immunosuppressive therapies.

Patients who are being treated for hepatitis C should not be treated differently than patients without hepatitis C. TNF inhibitors can be used in patients with hepatitis C when they are being treated for this viral infection. In patients with untreated hepatitis C, DMARDs are recommended over TNF inhibitors. Methotrexate and leflunomide should be avoided due to potential effects on the liver; instead, hydroxychloroquine or sulfasalazine should be considered.[43]

Malignancy

In patients with previous melanoma and nonmelanoma skin cancer, DMARDs are preferred over biologic agents and tofacitinib. DMARDs are less immunosuppressive than biologics, decreasing the risk of skin cancer with DMARDs compared with other RA therapies. However, in patients with low-grade skin cancer with history of prior treatment, biologics could be considered with close monitoring of the skin by a dermatologist.

In patients with previously treated lymphoproliferative disorders, rituximab use is recommended over TNF inhibitors because of the known increased risk of lymphoma with TNF inhibitors. Also, rituximab is an FDA-approved treatment for some lymphoproliferative disorders. Combination DMARDs, abatacept, or tocilizumab can be considered over TNF inhibitors. Patients with a history of previously treated solid organ malignancy should be treated as patients without this history.[43]

Heart Failure

TNF inhibitors should be avoided in patients with NYHA II, III, or IV heart failure because of the potential for TNF inhibitors to worsen heart failure or cause new-onset heart failure. If patients develop signs of worsening heart failure on TNF inhibitors, this therapy should be discontinued. Combination DMARDs, non-TNF biologics, or tofacitinib would be recommended as alternative therapies.[43]

Comorbidity Management

Cardiovascular Risk Reduction

RA poses as a risk factor for CV disease; this is likely the result of multiple factors present in patients with RA, including chronic inflammation. Therefore, part of RA management is to also manage cardiovascular disease risk. To lower CV disease risk, RA disease activity should be as low as possible. Lifestyle recommendations should be discussed with patients including smoking cessation, regular exercise, and healthy diet.

Other factors that contribute to CV disease—such as hypertension, hyperlipidemia, and diabetes—should be screened for and treated appropriately. NSAIDs should be used with caution, especially in patients with established CVD. Glucocorticoid use should be minimized and tapered to the lowest possible dose due to their potential ill effects on blood glucose and blood pressure.[91]

Osteoporosis

RA is associated with an increased incidence of osteoporosis, falls, and fractures. Glucocorticoid use can increase the potential for these risks. Published recommendations for osteoporosis screening in patients with RA vary greatly. The American Association of Clinical Endocrinologists recommends screening all postmenopausal women with an increased risk of secondary osteoporosis, including those with RA. Canadian recommendations include osteoporosis screening for all patients older than 50 years of age who have RA.[92]

In patients with RA who have low bone mineral density, treatment should be considered based on estimated 10-year probability of a major osteoporotic fracture or hip fracture risk.[92] Vitamin D supplementation and calcium intake should also be assessed and optimized.

According to the ACR, patients on long-term glucocorticoids who are 40 years of age or older should have bone mineral density testing at least within 6 months of initiating glucocorticoids, and fracture risk should be estimated using FRAX. In patients younger than 40 years of age, bone mineral density testing should be considered at least within 6 months of initiating glucocorticoids if the patient has a history of an osteoporotic fracture or has significant risk factors for developing osteoporosis.[93]

Immunizations

Live vaccines should not be given during treatment with biologics but instead should be given before starting therapy when possible and avoided for at least 3 months after immunosuppressants are discontinued.[6] This is because of the inability of the immunocompromised patient to mount an appropriate immune response to the vaccine. Live vaccines can be given to patients on methotrexate (the doses used in RA typically do not produce enough immunosuppression to cause concern), leflunomide, sulfasalazine, and hydroxychloroquine. Inactivated vaccines can be administered while patients are on conventional DMARDs, TNF and non-TNF biologics, and JAK inhibitors; however, efficacy of the vaccine may be reduced if the patient is on methotrexate or biologic agents.[43]

Several influenza vaccines are available, including inactivated influenza vaccine (IIV), recombinant influenza vaccine (RIV), and the intranasal live-attenuated influenza vaccine (LAIV). Patients with RA should receive the influenza vaccine yearly before initiating and during therapy. The IIV and RIV can be administered to all patients on conventional DMARDs, TNF inhibitors, non-TNF biologics, and JAK inhibitors and who do not have other contraindications to the vaccine. The high-dose inactivated influenza vaccine that is licensed for individuals 65 years of age or older can be given to RA patients regardless of concomitant RA drug therapy.

The available hepatitis B vaccines—either a three-dose series over 6 months (Recombivax HB, Engerix-B), a newer recombinant product (Heplisav-B) that is given in two doses 1 month apart, or a three-dose series in combination with hepatitis A protection (Twinrix)—are licensed for use in adults. These can be given before initiating or while on therapy for RA, but patients on immunosuppressive agents may have a reduced response to the vaccine. The series can be completed as directed in product labeling without regard for RA therapy. The Centers for Disease Control and Prevention (CDC) immunization schedule states that Heplisav-B can be used as a substitute for a dose of a three-dose series hepatitis B vaccine; however, two doses of Heplisav-B still need to be given at least 4 weeks between doses in order for the series to be complete.

Tetanus, diphtheria, acellular pertussis (Tdap) is an inactivated vaccine that should be given to adults who have not received a dose of Tdap as an adult or child. A dose of Td or Tdap is then recommended every 10 years.

The two inactivated pneumococcal vaccines, the pneumococcal polysaccharide vaccine (PPSV, Pneumovax 23) and the pneumococcal conjugated vaccine (PCV, Prevnar 13), should be administered to patients with acquired immunodeficiencies, including patients with RA who are receiving biologic therapy. PCV13 is administered to such patients who are 19 to 64 years of age followed by PPSV23 at least a year later. Another dose of PPSV23 should be given 5 years later. At age 65 or older, an additional dose of PPSV23 should be given at least 5 years after the most recent dose of PPSV23.[94,95]

The Advisory Committee on Immunization Practices (ACIP) no longer recommends routine PCV13 use for all adults >65 years old. Instead, shared clinical decision making for PCV13 use is recommended for adults age 65 years and older who do not have an immunocompromising condition. Due to the nature of RA and its immunocompromising therapies, the updated recommendation does not change immunization practices with respect to this health condition.[96]

A recombinant, adjuvant zoster vaccine to prevent herpes zoster was approved in 2017 (Shingrix) and is recommended for adults aged 50 years and older. It is administered as two doses at 0 and 2 to 6 months. The safety of this vaccine in patients with certain comorbid conditions, including RA, still needs to be determined.[97,98] An older zoster vaccine, Zostavax, is a live vaccine that is contraindicated in patients with RA who are on immunosuppressive therapies; Shingrix is now the preferred vaccine over Zostavax, according to the CDC.[9]

EVALUATION OF THERAPEUTIC OUTCOMES

⑨ An assessment of disease activity should be conducted at baseline and at each follow-up visit for patients with RA to evaluate disease control and therapeutic response. The evaluation of therapeutic outcomes should be based largely on the patient’s subjective improvement of RA symptoms with respect to joint pain, swelling and tenderness, morning stiffness, and fatigue, as well as on a patient’s ability to perform activities of daily living. A physical examination should also be conducted at each visit to evaluate the number of swollen and/or tender joints to obtain objective data. This can also help clinicians evaluate loss of joint mobility and deformity. As detailed in Table 111-3, several useful tools can guide clinicians in the objective measurement of disease activity.

TABLE 111-3

Assessment Tools to Measure Rheumatoid Arthritis Disease Activity

Assessment Tool	Scale	High Disease Activity	Moderate Disease Activity	Low Disease Activity	Remission
Clinical Disease Activity Index (CDAI)	0 to 76	>22	>10 to 22	>2.8 to 10	≤2.8
Disease Activity Score (DAS28)	0 to 9.4	>5.1	≥3.2 to ≤5.1	≥2.6 to <3.2	<2.6
Patient Activity Scale (PAS) or PASII	0 to 10	≥8.0	>3.7 to <8.0	>2.5 to 3.7	0 to 2.5
Routine Assessment of Patient Index Data 3 (RAPID-3)	0 to 10	>4.0 to 10	>2 to 4	>1.0 to 2.0	0 to 1.0
Simplified Disease Activity Index (SDAI)	0 to 86	>26	>11 to ≤26	>3.3 to ≤11.0	≤3.3

Laboratory monitoring of acute phase reactants such as CRP and ESR can be useful in assessing inflammation. Plain radiographs of the hands, wrists, and forefeet should be obtained at baseline as well as every 2 years in patients with low disease activity or in remission. Little-to-no evidence of RA disease progression should be evident on this imaging if drug therapy is effective. Imaging may be needed more frequently in patients with moderate or high disease activity. If patients have radiographic changes on imaging that indicate RA disease progression—such as periarticular osteopenia, bone erosions, or joint space narrowing—drug therapy should be modified.[98]

It is also important to monitor and assess for adverse effects of the medications used to treat RA as detailed in Table 111-4.

TABLE 111-4

Adverse Drug Reactions and Monitoring Recommended for Disease-Modifying Antirheumatic Drugs

Drugs	Adverse Drug Reactions	Initial Monitoring	Maintenance Monitoring
NSAIDs	GI ulceration, bleeding, and perforation, renal damage	SCr, CBC every 2-4 weeks after starting therapy	Same as initial plus stool guaiac every 6-12 months
Corticosteroids	Fluid retention, hyperglycemia, hypertension, behavioral and mood changes, increased appetite, weight gain, electrolyte imbalances, impaired healing, hirsutism, Cushing syndrome, HPA axis suppression, osteonecrosis of femoral and humeral heads, osteoporosis and fractures, myopathy, glaucoma, cataracts	Glucose, CBC periodically, blood pressure every 3-6 months	Same as initial
Hydroxychloroquine	Retinal damage, rash, diarrhea	Ophthalmologic exam (fundus examination plus visual fields and spectral-domain optical coherence tomography if maculopathy present) within 5 years of starting therapy	Ophthalmologic exam annually if risk factors for retinal damage present or annually beginning after 5 years of use if no risk factors
Methotrexate	Infection, hepatic fibrosis, cirrhosis, interstitial pneumonitis, stomatitis, rash, GI perforation, diarrhea, thrombocytopenia, leukopenia	SCr, CBC with differential, AST, ALT, hepatitis B and C screening, tuberculosis screening	SCr, CBC with differential, AST, ALT, every 2-4 weeks for 3 months after starting or following a dose increase, then every 8-12 weeks during 3-6 months of therapy, and every 12 weeks after 6 months of therapy, signs of infection
Leflunomide	Hepatitis, diarrhea/nausea, alopecia, elevated blood pressure	CBC with differential, SCr, ALT, AST, blood pressure	CBC with differential, SCr, ALT, AST every 2-4 weeks for 3 months after starting or following a dose increase, then every 8-12 weeks during 3-6 months of therapy, and every 12 weeks after 6 months of therapy; blood pressure periodically
Sulfasalazine	Rash, nausea, vomiting, diarrhea, photosensitivity, alopecia	CBC with differential, SCr, ALT, AST	CBC with differential, SCr, ALT, AST every 2-4 weeks for 3 months after starting or following a dose increase, then every 8-12 weeks during 3-6 months of therapy, and every 12 weeks after 6 months of therapy
Tocilizumab	Local injection-site reactions, infection, malignancy, GI perforation, neutropenia, thrombocytopenia	Tuberculosis screening, hepatitis B screening, CBC with differential, AST, ALT, FLP	AST, ALT, CBC with differential every 4-8 weeks after starting then every 3 months; FLP after 4-8 weeks of starting then every 6 months, signs/symptoms of infection and malignancy

Upadacitinib	Infection, malignancy, GI perforations, upper respiratory tract infections, neutropenia, lymphocytopenia, nausea, hepatotoxicity, CPK elevation, thrombosis, increased cholesterol	Tuberculosis screening, hepatitis screening, CBC with differential, LFTs, FLP	CBC with differential, FLP, LFTs, hepatitis screening periodically
Baricitinib	Infection, malignancy, upper respiratory tract infections, herpes zoster infection, hepatotoxicity, hematologic toxicities including anemia, gastrointestinal perforations, thrombosis, lymphocytopenia, neutropenia, increase in SCr and CPK	CBC with differential, LFTs, FLP, tuberculosis, and hepatitis screening	CBC with differential, LFTs, FLP periodically
Anakinra	Local injection-site reactions, infection, malignancy	CBC with differential, tuberculosis screening, SCr, hepatitis B screening	CBC with differential every 3 months up to 1 year, SCr periodically, signs/symptoms of infection and malignancy
Etanercept, adalimumab, golimumab, certolizumab	Local injection-site reactions, infection, malignancy	Tuberculosis screening, hepatitis B screening, CBC with differential	Periodic skin examination, signs/symptoms of infection and malignancy, CBC with differential periodically
Infliximab	Immune reactions, infection, malignancy	Tuberculosis screening, hepatitis B screening, CBC with differential, LFTs	CBC with differential, LFTs, signs/symptoms of infection and malignancy
Rituximab	Immune reactions, infection, malignancy	Tuberculosis screening, hepatitis B screening, CBC with differential	CBC with differential prior to each treatment course and at 2- to 4-month intervals, signs/symptoms of infection
Abatacept	Immune reactions, infection, malignancy	Tuberculosis screening, hepatitis B screening	Signs/symptoms of infection and malignancy
Tofacitinib	Infection, malignancy, GI perforations, upper respiratory tract infections, headache, diarrhea, nasopharyngitis	Tuberculosis screening, hepatitis B screening, CBC with differential, Hgb, LFTs, FLP, HR, and blood pressure	CBC with differential and Hgb after 4-8 weeks and every 3 months, FLP after 4-8 weeks and periodically, LFTs periodically, periodic skin examinations, HR and blood pressure, signs/symptoms of infection and malignancy
Sarilumab	Local injection-site reactions, infection, malignancy	Tuberculosis screening, hepatitis B screening, CBC with differential, LFTs, lipid panel	CBC with differential and LFTs 4-8 weeks after starting and then every 3 months, FLP 4-8 weeks after starting and every 6 months during therapy, signs/symptoms of infection and malignancy

ALT, alanine transaminase; AST, aspartate transaminase; CBC, complete blood count; CPK, creatine phosphokinase; FLP, fasting lipid panel; GI, gastrointestinal; HPA, hypothalamic–pituitary–adrenal; LFTs, liver function tests; SCr, serum creatinine.

CONCLUSION

Rheumatoid arthritis is an autoimmune condition that impacts approximately 1% of the population. It is a systemic, progressive disease that can lead to disability and decreased quality of life. The course of therapy is variable but includes both nonpharmacologic and pharmacologic therapies. A patient-centered, comprehensive treatment plan should be initiated as soon as a diagnosis is established to target disease remission or low disease activity. Though a treatment plan should be created with a trained rheumatologist, other clinicians should be utilized for their expertise, such as social work, mental health, and physical/occupational therapy. Chosen pharmacologic treatment is dependent on level of disease activity, past medication trials, comorbidities, and patient-preference. Though the etiology of RA is unclear, we can expect further research to be conducted to determine its cause to help design additional targeted therapies, including expansion of the role of biosimilars

ABBREVIATIONS

ACIP	Advisory Committee on Immunization Practices
ACPA	anticitrullinated protein antibodies
ACR	American College of Rheumatology
ALC	absolute lymphocyte count
ALT	alanine aminotransferase
AST	aspartate aminotransferase
ANA	antinuclear antibody
ANC	absolute neutrophil count
ANTI-CCP	anti-citrullinated C protein
BID	twice daily
CBC	complete blood count
CPK	creatine phosphokinase
CRP	C-reactive protein
CT	computed tomography
CYP450	cytochrome P450
DEXA	dual-energy x-ray absorptiometry
DMARDs	disease-modifying antirheumatic drugs
eGFR	estimated glomerular filtration rate
ESR	erythrocyte sedimentation rate

EULAR	European League Against Rheumatism
EX	extended release
FDA	Food and Drug Administration
GI	gastrointestinal
HLA	human leukocyte antigen
Hgb	hemoglobin
HPA	hypothalamic–pituitary–adrenal
IgG	immunoglobulin G
IL	interleukin
IM	intramuscular
IR	immediate release
IV	intravenous
ILD	interstitial lung disease
JAK	Janus kinase
LFTs	liver function tests (includes AST/ALT, T bilirubin, Alkaline Phosphatase)
LGL	large granular lymphocyte leukemia
MO	month
MTX	methotrexate
NSAIDs	nonsteroidal anti-inflammatory drugs
NYHA	New York Heart Association
PBM	pharmacy benefit managers
RA	rheumatoid arthritis
RANKL	receptor activator of NFkB ligand
RF	rheumatoid factor
SCr	serum creatinine
SubQ	subcutaneous

TNF	tumor necrosis factor
ULN	upper limit of normal
US	ultrasound

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements about rheumatoid arthritis is true?
    A. Men are twice as likely to have rheumatoid arthritis compared with women.
    B. Rheumatoid arthritis generally presents in the third decade of life.
    C. The mortality rate of rheumatoid arthritis is increased compared to the general population.
    D. Cigarette smoking has not been shown to impact disease activity.
2. Which of the following signs/symptoms are consistent with the clinical presentation of rheumatoid arthritis?

A. Red, swollen bilateral phalangeal joints

B. Joint stiffness present only in the evenings

C. Unilateral joint pain present in the left knee

D. Bony enlargements

3. Which of the following is a routinely recommended nonpharmacologic therapy for rheumatoid arthritis?

A. Sodium restriction

B. Increased physical activity

C. Protein restriction

D. Increased vitamin B intake

4. Which of the following is considered a treatment goal for rheumatoid arthritis management?

A. Increase social involvement

B. Decrease disability

C. Low disease activity/disease remission

D. All the above

5. Which of the following is *not* a TNF inhibitor?

A. Adalimumab (Humira)

B. Golimumab (Simponi)

C. Certolizumab (Cimzia)

D. Tocilizumab (Actemra)

6. Which of the following biologics is manufactured as an intravenous (IV) infusion?

A. Etanercept (Enbrel)

B. Adalimumab (Humira)

C. Infliximab (Remicade)

D. Golimumab (Simponi)

7. Which of the following is an appropriate patient-counseling point for methotrexate?

A. It is important to complete all laboratory follow-up as instructed by your provider.

B. This medication should be taken daily.

C. You may continue this medication if you become pregnant.

D. This medication can cause macular damage.

8. Which of the following therapies for rheumatoid arthritis has the lowest pregnancy risk?

   A. Methotrexate (Rheumatrex)

   B. Sulfasalazine (Azulfidine)

   C. Leflunomide (Arava)

   D. Rituximab (Rituxin)

9. Which of the following vaccinations should be avoided in a patient being treated with a biologic agent for rheumatoid arthritis?

   A. Intranasal influenza

   B. Intramuscular influenza

   C. Hepatitis B

   D. Tetanus, diphtheria, acellular pertussis

10. Which of the following therapies for rheumatoid arthritis should be avoided in a patient with advanced heart failure?

   A. Abatacept (Orencia)

   B. Tocilizumab (Actemra)

   C. Golimumab (Simponi)

   D. Tofacitinib (Xeljanz)

11. Rapid elimination of leflunomide can be completed with which of the following therapies?

   A. Carbidopa

   B. Chlorambucil

   C. Cholestyramine

   D. Cholecalciferol

12. Which of the following would be an appropriate counseling point for adalimumab (Humira)?

   A. This medication can cause high blood pressure.

   B. This medication should not be interrupted for any reason.

   C. This medication should be administered monthly.

   D. This medication can be given with methotrexate.

13. RT is a 66-year-old man with well-controlled rheumatoid arthritis on tocilizumab therapy. His primary care provider inquires about appropriate immunizations. What do you recommend?

   A. Influenza IM (Fluzone), hepatitis B (Recombivax), PCV 13 (Prevnar)

   B. Influenza intranasal (Flumist), PPSV 23 (Pneumovax)

   C. Influenza IM (Fluzone), herpes zoster (Zostavax)

   D. The patient should not receive any immunizations while taking tocilizumab

14. BG is a 57-year-old woman with newly diagnosed rheumatoid arthritis. After shared decision making, she will be starting methotrexate and enrolling in a physical therapy program. What laboratory monitoring needs to be completed while she is on therapy?

    A. CBC, TSH, SCr + eGFR

    B. TSH, SCr + eGFR, AST/ALT

    C. CBC, A1c, TSH

    D. CBC, SCr + eGFR, AST/ALT

15. TK is 69-year-old woman with type 2 diabetes, chronic obstructive pulmonary disease, inflammatory bowel disease, and established rheumatoid arthritis. She has an allergy to sulfa drugs and penicillin. Her disease activity scores remain elevated despite optimized methotrexate therapy. What would be an appropriate therapeutic intervention to help her achieve her goal of low disease activity?

    A. Add sulfasalazine to methotrexate.

    B. Add adalimumab to methotrexate.

    C. Stop methotrexate and add abatacept.

    D. Add abatacept to methotrexate.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The mortality rate in patients with rheumatoid arthritis is increased compared with the general population, with 3 to 10 fewer years of expected life in those with this disease. Rheumatoid arthritis affects women twice as often as men and typically presents in the fifth decade of life. Cigarette smoking has also been tied to increased disease activity, increased biomarkers, and poor prognoses. See "Epidemiology" and "Etiology" sections of this chapter for additional information.

2. **A.** Rheumatoid arthritis typically involves bilateral, multiple small joints. Joint stiffness typically starts in the morning and can last throughout the day. Boney enlargements are typically seen with osteoarthritis. See "Clinical Presentation" section of this chapter for additional information.

3. **B.** Increased physical activity is recommended in patients with rheumatoid arthritis; the other options are not applicable to management of this condition. See "Treatment" section of this chapter for additional information.

4. **D.** All the options are reasonable goal of care. Other goals include decrease joint pain/stiffness and decreased disability. See "Treatment" section of this chapter for additional information.

5. **D.** Tocilizumab is a monoclonal antibody that inhibits the binding of the proinflammatory cytokine IL-6 to its receptor. All other options are TNF inhibitors. See "Treatment" section of this chapter for additional information.

6. **C.** Only infliximab (Remicade) is administered IV. All other options are manufactured as subcutaneous injections administered using pens or syringes. See "Treatment" section of this chapter or Table 111-2 for additional information.

7. **A.** Methotrexate requires routine laboratory work that is important for monitoring therapy. See "Treatment" section of this chapter for required blood work and time frames. Methotrexate is dosed weekly, not daily, for its rheumatoid arthritis indication. It is contraindicated in pregnancy. Option D is a counseling point for hydroxychloroquine and is not relevant for methotrexate.

8. **B.** Sulfasalazine crosses the placenta and is present in breast milk but can be used in pregnant and nursing mothers with caution. Methotrexate and leflunomide are contraindicated in pregnancy, and rituximab is one of several agents considered potentially unsafe to use during pregnancy. See "Treatment" section of this chapter for more information.

9. **A.** The intranasal influenza vaccine is a live-attenuated influenza product, and live vaccines should not be administered to patients taking biologic

therapy. If possible, live vaccines should be administered to patients before starting therapy. None of the other options are live vaccines. See "Treatment" section of this chapter for more information.

10. **C.** Golimumab is a TNF inhibitor, and TNF inhibitors as a class should be avoided in patients with advanced heart failure. The other options are not TNF inhibitors and thus can be used for rheumatoid arthritis management in this patient population. See "Treatment" section of this chapter for more information.

11. **C.** Cholestyramine is a bile acid sequestrant that can be used to bind leflunomide and remove it from the body in the case of elevated laboratory values or incidental pregnancy. This is useful as leflunomide otherwise has a long half-life. The other options are dopaminergic, antineoplastic, and vitamin supplement therapies. See "Treatment" section of this chapter for more information.

12. **D.** Adalimumab (Humira) can be given with or without methotrexate. It is dosed weekly or biweekly. Biologics should be held periprocedurally and during an acute infection. This medication most commonly causes injection site reactions (itching, bruising, minor bleeding, redness) and headache. See "Treatment" section for more information and the postclass learning activity in this chapter for additional guidance.

13. **A.** Influenza IM (Fluzone), hepatitis B (Recombivax), and PCV 13 (Prevnar) are all killed vaccines that can be administered before or during biologic therapy treatment. Influenza intranasal vaccine (Flumist) and the older herpes zoster product (Zostavax) are live-attenuated vaccines that should not be given to immunocompromised patients on biologics; in addition, Flumist is licensed by the FDA for use in patients ages 2 through 49 years. See "Treatment" section of this chapter for additional information.

14. **D.** CBC with differential, hepatic enzymes, and renal function should be monitored every 2 to 4 weeks for 3 months after initiation or following a dose increase, then every 8 to 12 weeks during 3 to 6 months of therapy, and every 12 weeks after 6 months of therapy. TSH and A1c are not routine labs required for methotrexate monitoring. See "Treatment" section of this chapter for additional information.

15. **B.** Adalimumab can be used with or without methotrexate and may provide dual treatment for both inflammatory bowel disease and rheumatoid arthritis. Sulfasalazine should not be recommended in patients with a sulfa allergy. Abatacept should not be recommended in patients with chronic obstructive pulmonary disease. See "Treatment" section of this chapter for additional information.

Chapter 112: Osteoporosis

Mary Beth O’Connell; Jill S. Borchert; Erin M. Slazak; Joseph P. Fava

KEY CONCEPTS

KEY CONCEPTS

① Osteoporosis is a public health epidemic that affects all ages, genders, races, and ethnicities. Lifestyle behaviors, diseases, and medications should be reviewed to identify the risk factors for developing osteoporosis and osteoporotic fractures. Healthcare professionals should identify and resolve reversible risks. Secondary causes of bone loss should be explored, especially for patients with early-onset or severe osteoporosis.

② Bone physiology and pathophysiology are complex involving coupled bone resorption and formation in bone remodeling processes. These processes result from many different cell lines, transmitters, pathways, and biofeedback systems. As these processes become more delineated, additional targets are identified for medications.

③ All patients taking medications known to increase bone loss, falls, and fractures should practice a bone-healthy lifestyle, be evaluated for a switch to a safer alternative medication, and/or be considered for osteoporosis therapy. The most common causes of medication-induced osteoporosis are long-term oral glucocorticoids and certain chemotherapeutic agents.

④ Ten-year probabilities for a major osteoporotic and hip fracture can be estimated for women (postmenopausal to 90 years old) and men (50-90 years old) with the fracture risk assessment tool (FRAX) tool. This tool is a questionnaire that can be used in any setting, including pharmacies, health fairs, and clinics. Central bone mass densitometry can determine bone mass, predict fracture risk, and influence patient and provider treatment decisions.

⑤ Throughout life, everyone should practice a bone-healthy lifestyle, which emphasizes regular exercise, nutritious diet, tobacco avoidance, minimal alcohol use, and fall prevention to prevent and treat osteoporosis.

⑥ Treatment should be considered for postmenopausal women and men older than 50 years who have a low-trauma hip or vertebral fracture, T-score of −2.5 or less at the femoral neck, total hip, or spine, or low bone mass (T-score between −1.0 and −2.5) and a FRAX 10-year probability of major osteoporotic fracture of 20% or more or hip fracture of 3% or more. Patients with secondary causes might receive therapy at younger ages or higher T-scores.

⑦ The recommended dietary calcium intake for American adults is 1,000 to 1,200 mg of elemental calcium daily with diet as the preferred source. Supplements are added when diet is insufficient.

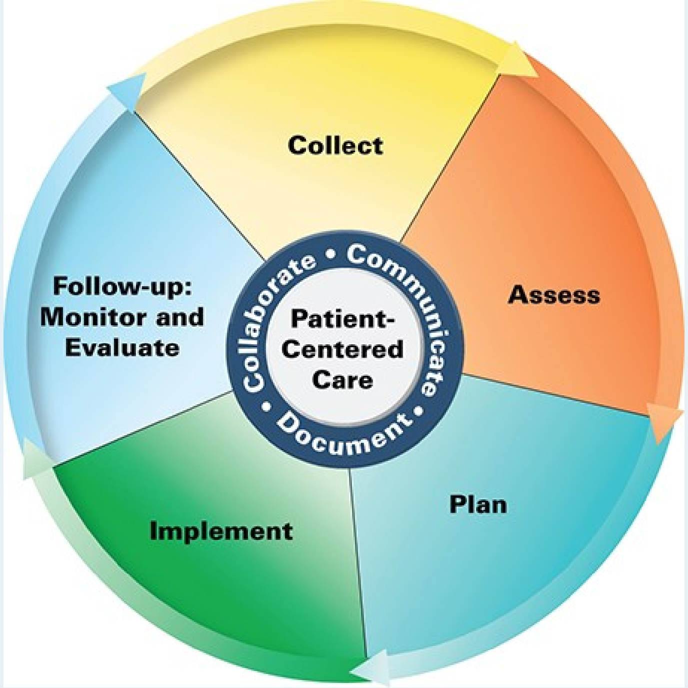
⑧ The recommended daily dietary vitamin D intake for American adults is 600 units and for older adults 800 units. Some organizations and guidelines recommend higher doses of at least 800 to 1,000 units daily. Vitamin D intake is achieved through sun exposure, fortified foods, and supplements. Vitamin D insufficiency and deficiency, defined as 25-hydroxyvitamin D (25[OH] vitamin D) concentrations of less than 30 ng/mL (mcg/L; 75 nmol/L) and less than 20 ng/mL (mcg/L; 50 nmol/L) respectively, are common in Americans. Higher vitamin D daily intakes and/or replenishment doses are then required.

⑨ Alendronate, risedronate, zoledronic acid, and denosumab decrease vertebral, hip, and nonvertebral fractures and are first-line osteoporosis treatments for those with high fracture risk. Therapy continues for about 5 years in mild osteoporosis and 5 to 10 years in moderate-to-severe osteoporosis. Other antiresorptive (ibandronate, raloxifene), anabolic (abaloparatide, teriparatide), and combination anabolic and antiresorptive (romosozumab) medications are alternatives. These medications decrease osteoporotic fracture risk but not hip fractures. In patients with very high fracture risk, sequential therapy with abaloparatide, romosozumab, or teriparatide followed by an antiresorptive agent is recommended.

⑩ Adherence to osteoporosis medications is suboptimal. Poor adherence is associated with less fracture prevention. Healthcare professionals should assess medication administration technique and adherence at each visit, provide education, and resolve medication-related problems.

PATIENT CARE PROCESS

Patient Care Process for Osteoporosis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, race, ethnicity, postmenopausal status)
- Medical history (personal and family; eg, maximum height, falls, fractures, dental issues, gastroesophageal reflux/heartburn, and for women age at menarche and menopause)
- Social history (eg, tobacco and alcohol use, physical activity, and dietary habits, including calcium-containing food and beverage intake)
- Current medications including calcium and vitamin D, dietary supplements, multivitamins, and herbal product use
- Past medications (eg, hormone therapy and medications causing osteoporosis; see Table 112-3)
- Objective data
  - Height, weight
  - Laboratory results (see Table 112-4) and secondary causes
  - Central dual-energy x-ray absorptiometry (DXA) at the spine and hip
  - Fracture evidence (eg, vertebral fracture assessment [VFA], radiographs)

Assess

- Adequacy of dietary calcium and calcium/vitamin D supplement intakes
- Bone mineral density (BMD): Categorize lowest T-score as normal, low bone mass, or osteoporosis

- FRAX 10-year risk of major osteoporotic fractures and hip fracture
- Laboratory data and presence of secondary causes (see Tables 112-2 and 112-3)
- Patient preferences including injectable medications and concern about adverse effects
- Potential barriers to adherence (eg, administration route, frequency, cost, health literacy)

Plan

- Medication regimen including specific agent, dose, route, frequency, and duration (see Fig. 112-3, Tables 112-7 and 112-8), and calcium and vitamin D supplements as necessary.
- Monitoring parameters including efficacy (eg, BMD, fracture, 25(OH)-vitamin D concentration) and safety (eg, common and serious adverse effects, serum creatinine, calcium). Include frequency and timing of follow-up.

Implement*

- Provide patient education regarding treatment plan (eg, purpose of treatment, dietary calcium sources, medication-specific administration/injection technique in patient's primary language, adverse effects) (see Tables 112-7 and 112-8)
- Consider risk communication tool to explain medication benefit and rare adverse effects
- Schedule laboratory tests as needed and DXA (generally 2-5 years after initiation)
- Schedule referrals when appropriate (eg, physical therapist for fall prevention, dietitian)
- For zoledronic acid, coordinate with infusion center for administration
- For nongeneric therapies, coordinate prior authorization process as necessary

Follow-up: Monitor and Evaluate*

- Patient adherence to treatment plan and administration instructions
- Presence of adverse effects (see Table 112-8)
- BMD, fractures, falls, and laboratory parameters
- Changes in habits (eg, dietary calcium, exercise, alcohol, and tobacco use)
- Re-evaluate duration of therapy after 1 year (romosozumab), 2 years (abaloparatide, teriparatide), 3 years (intravenous bisphosphonate), 5 years (oral bisphosphonate), or as suggested by response to therapy and adverse effects

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Create a team of three classmates. Each team member selects one of the below patients to work-up. This activity is useful to enhance your understanding of the COLLECT, ASSESS, and PLAN steps in the patient care process, the osteoporosis treatment algorithm, and individualization of patient care.

In your patient work-up:

- Identify osteoporosis risks and secondary causes.
- Calculate a FRAX score (https://www.sheffield.ac.uk/FRAX/).
- Estimate calcium intake (https://www.osteoporosis.foundation/educational-hub/topic/calcium-calculator).
- Determine the calcium and vitamin D Institute of Medicine recommended daily intakes and deficits.
- Develop a prevention or treatment plan.
- Present your patient's risk factors, assessments, and treatment plan to each other.
- Compare and contrast these three women's cases and treatment plans.

Patient 1: A 57-year-old White, nonsmoking female living in the United States. Patient's weight is 77 kg and height is 5 ft 6 in (168 cm). She has had no previous fractures and has no family history of fracture. Her T-scores are femoral neck -2.2 and spine -2.0. She has hypertension, hyperlipidemia, and GERD. The patient's current medications are omeprazole (Prilosec), atorvastatin (Lipitor), and amlodipine (Norvasc). The patient reports no vitamins or supplements. The patient drinks 1 glass of milk daily and eats 1 serving of yogurt daily. She does not drink alcohol.

Patient 2: A 67-year-old Hispanic female living in the United States. Patient's weight is 77 kg and height is 5 ft 6 in (168 cm). She has had no previous fractures but her mother had a hip fracture. Her T-scores are femoral neck -2.4 and spine -2.0. She has hypertension, diabetes Type 2, and hyperlipidemia. The patient's current medications are canagliflozin (Invokana), atorvastatin (Lipitor), and enalapril (Vasotec). The patient reports taking Centrum(R) Silver(R) Women's 50+ every day. Social history: the patient drinks 1 glass of milk daily and eats 1 serving of yogurt daily. She smokes tobacco products but does not drink alcohol.

Patient 3: A 77-year-old Asian, female living in the United States. Patient's weight is 77 kg and height is 5 ft 6 in (168 cm). She has had no previous fractures and no family history of fracture. Her T-scores are femoral neck -2.6 and spine -2.9. She has diabetes type 2, rheumatoid arthritis, hypertension, and lactose intolerance. The patient's current medications are metformin (Glucophage), lisinopril (Prinivil), adalimumab (Humira), and celecoxib (Celebrex) as needed. Prior to adalimumab, she had used prednisone 5 to 10 mg daily for over 5 years. The patient uses no vitamins or supplements. The patient drinks 1 glass of fortified soy milk daily and eats 1 serving of tofu daily. She does not drink alcohol or smoke.

INTRODUCTION

① Osteoporosis is a bone disorder characterized by low bone density, impaired bone architecture, and compromised bone strength that predisposes a person to increased fracture risk. Osteoporosis is a major public health threat, with about 50% of people 50 years of age and older expected to develop this disease.[1] In the United States, 10.2 million Americans are estimated to have osteoporosis.[2] An additional 43.4 million Americans are estimated to have low bone density and are at risk for osteoporosis. Attention to bone health is required throughout life. Osteoporosis and osteoporotic fractures are multifactorial conditions, beginning at birth with genetics and continuing throughout life due to health behaviors that influence bone growth and maintenance, skeletal factors that lead to compromised bone strength, and nonskeletal factors that lead to falls (Fig. 112-1). Healthcare professionals should educate people about bone-healthy lifestyles and empower them to practice these health behaviors. Osteoporosis is underdiagnosed and undertreated. Bone health screenings, osteoporosis prevention programs, accurate diagnoses, and optimal medication management are needed to prevent and treat osteoporosis and prevent fractures.

Editors' note: In this and other chapters in Pharmacotherapy*, references to biologic gender (as assigned at birth) are used based on prior literature being discussed or anatomical or physiologic differences. We recognize that not all individuals identify with their gender at birth, and to the degree possible when discussing therapeutics, we avoid use of references to gender. In this chapter on Osteoporosis, "men" and "women" are used in discussing prior studies, published guidelines, and other recommendations for diagnosis and treatment based on biological gender and do not necessarily reflect an individual's gender identity.*

EPIDEMIOLOGY

① Low bone density, osteoporosis, and osteoporotic fractures are common in all people, with race and ethnic differences in osteoporosis detection, treatment and outcomes likely due to health disparities.[3,4] The prevalence of osteoporosis in women is 16.5%.[4] Low bone density was estimated to occur in 45 % of non-Hispanic White, 43% of Mexican American, and 30% of non-Hispanic Black women aged 50 years and older.[3,5] Osteoporosis affects 13.4% of Mexican American, 10.2% of non-Hispanic White, and 4.9% of non-Hispanic Black women aged 50 years and older. Disease prevalence greatly increases with age; from 7% in women aged 50 to 59 years to 35% in women aged 80 years and older.[4] White American (17%) and Hispanic American (14%) women have the highest fragility fracture rate followed by Black American (6%) women.

Although more prevalent in women, men can also have low bone density and osteoporosis. Based on FRAX estimates, approximately 16% of men aged 50 years and older have low bone density rising to 46% in men aged 80 years and older.[6] Osteoporosis rises from 3% in men aged 50 to 59 years to 11% in men aged 80 years and older.[5] Osteoporosis prevalence also varies by race and ethnicity in men: 6% in Mexican American men, 4% in non-Hispanic White American men, and 1% in non-Hispanic Black American men.[3,5]

Fragility wrist and vertebral fractures are common throughout adulthood, with hip fractures more common in older adults. Although osteoporosis is common in adults with fractures, 12% of fracture patients have normal BMD and 52% have low bone density, supporting fractures can occur in all.[7]

Gender differences in osteoporotic fractures exist with 70% occurring in women and 30% in men.[2] As a woman ages, her risk of any fracture increases from 10% at age 50 years to 22% at 80 years old; with hip fractures increasing from 0.3% to 9% over the same time frame.[8] For men over the same time frame, fracture risk increases from 7% to 8% and hip fracture increases from 0.2% to 3%. Fracture outcomes are worse for people of color.[3]

Osteoporosis creates an economic health burden. In 2011, 1.7 million hospitalizations occurred for fragility fractures with 3 million osteoporotic fractures expected in 2025.[9] By 2025, osteoporosis treatment costs are estimated to be about $25 billion.[2] Because of associated morbidity, hip fracture is the most costly complication of osteoporosis, accounting for almost 72% of fracture costs. Osteoporosis costs exceed costs for breast cancer, heart attack, or stroke.

ETIOLOGY

① Figure 112-1 depicts a model describing osteoporosis and fracture etiology. The major risk factors (see Table 112-1) influencing bone loss are hormonal status, genetics, exercise, aging, nutrition, lifestyle, concomitant diseases, and medications. Nonhormonal risk factors are similar between women and men

TABLE 112-1

Risk Factors for Osteoporosis and Osteoporotic Fractures

Low bone mineral density (BMD)[a]
Female sex[a]
Advanced age[a]
Race/ethnicity[a]
History of a previous fragility (low-trauma) fracture including radiographic vertebral fracture as an adult[a] (especially clinical vertebral fracture or hip fracture)
Osteoporotic fracture in a first-degree relative (especially parental hip fracture[a])
Low body weight or body mass index[a]
Premature menopause
Secondary osteoporosis[a,b]
Rheumatoid arthritis[a]
Past or present systemic oral glucocorticoid therapy (prednisolone 5 mg daily or more for > 3 months)[a,c]
Current smoking[a,c]
Alcohol intake of 2 or more drinks/day[a,c]
Low calcium intake
Low physical activity or immobilization
Vitamin D insufficiency and deficiency
Recent falls
Cognitive impairment
Impaired vision

[a] Factors included in World Health Organization fracture risk assessment tool (FRAX).

[b] Secondary causes included in the FRAX tool are type 1 diabetes, osteogenesis imperfecta as an adult, long-standing untreated hyperthyroidism, hypogonadism, premature menopause, chronic malnutrition, malabsorption, and chronic liver disease.

[c] Risk is higher with greater exposure.

Data from References 2, 4, 10–13.

Low Bone Density

BMD is a major predictor of fracture risk. Every standard deviation decrease in BMD in women represents a 10% decrease in bone mass and a 1.6- to 2.6-fold increase in fracture risk.[2] In contrast, increasing peak bone mass in younger years by 10% was estimated to create 13 more years without a fracture in older women.[16] (Low BMD can occur as a result of failure to reach a normal peak bone mass, bone loss, or both. Genetics accounts for 50% to 85% of peak bone mass variability.[4,14] Bone loss occurs when bone resorption exceeds bone formation, which also can result from high bone turnover when the number or depth of bone resorption sites greatly exceeds the rate and ability of osteoblasts to form new bone. Women and men begin to lose a small amount of bone mass starting in the third to fourth decade of life, about 0.5% to 1% per year.[12,14] During perimenopause and menopause, bone loss occurs predominantly due to increases in bone resorption. By age 80 years, 30% of a woman's bone mass is lost.[4] Older adults steadily lose bone mass as a consequence of an accelerated rate of bone remodeling combined with reduced bone formation.

Impaired Bone Quality

Bone strength is highly affected by the quality of the bone's composition and its structure and is a better predictor of fracture than BMD.[9] Changes in bone mass do not fully reflect changes in bone thinning and decreased connectivity, both related to strength. BMD explains only 70% of femur and 44% of spine bone strength. Even women with normal bone mass (3.4%) and low bone mass (5.3%) fracture, rates slightly lower than women with osteoporotic bone mass (6.8%). Accelerated bone turnover can increase the amount of immature bone that is not adequately mineralized. Sex differences exist with thinning of trabeculae, with aging in men causing less bone quality damage and impaired bone strength than in women.[12] With aging, fracture risk increases for a given T-score, partly related to bone quality changes; for example, at a T-score of −2.5, a 50-year-old postmenopausal woman has about a 4% probability of a hip fracture, whereas a 70-year-old woman has about a 9% probability.[23]

Falls

Each year, 15% to 45% of community-dwelling older adults and up to 60% of nursing home residents fall each year, with more women falling than men.[4,24] Hip fractures only occurred in 1% to 2% of falls; however, 90% of hip fractures resulted from a fall.[8,25] Falls lead to accidental death in about 70% of older adults.[24] Inpatient and outpatient fall care is expensive.[24] The risk factors for falls overlap with the risk factors for osteoporosis and osteoporotic fractures.[2,24] Environmental factors also contribute to falls (eg, electric cords, throw rugs, and poor lighting).

PATHOPHYSIOLOGY

Normal Bone Physiology

② The skeleton has two types of bone. Cortical bone makes up the majority of the skeleton (80%) and is found mostly in the long bones (eg, forearm and hip).[14] Trabecular bone is found mostly in the vertebrae and ends of long bones. This bone type is metabolically more active compared with cortical bone due to a much higher bone turnover rate because of its large surface area and honeycomb-like shape.

Bone is made of collagen and mineral components.[9,14] The collagen component gives bone its flexibility and energy-absorbing capability. The mineral component (mostly calcium and phosphorus) which accounts for 50% to 70% of bone mass gives bone its stiffness and strength. The correct balance of these substances is needed for bone to adequately accommodate stress and strain and resist fractures. Imbalances can impair bone quality and lead to reduced bone strength.

Bone strength reflects the integration of bone mass, bone strength and quality (composition and microarchitecture).[9,16] Bone mass increases rapidly throughout childhood and adolescence. Peak bone mass is attained by age 18 to 25 years. Peak bone mass is highly dependent on genetic factors, which accounts for 60% to 80% of the variability. The remaining 20% to 40% is influenced by modifiable factors such as nutritional intake (eg, calcium, vitamin D, and protein), exercise, adverse lifestyle practices (eg, smoking), hormonal status, and certain diseases and medications (see Tables 112-2 and 112-3). Optimizing peak bone mass is important for preventing osteoporosis. The higher the peak bone mass, the more bone a person can lose before being at an increased fracture risk. As the microarchitecture of bone deteriorates, the bone strength greatly decreases.

TABLE 112-2

Select Medical Conditions Associated with Osteoporosis in Children and Adults

Endocrine/Hormonal
Primary or secondary ovarian failure
Testosterone deficiency
Hyperthyroidism
Cushing's syndrome (hypercortisolism)
Growth hormone deficiency (in children)
Hyperparathyroidism
Diabetes, type 1 and type 2
Gastrointestinal
Nutritional disorders (eg, anorexia nervosa)
Malabsorptive states (eg, Crohn's disease, celiac disease, cystic fibrosis, gastrectomy, and bariatric surgery)
Chronic liver disease (eg, primary biliary cirrhosis)
Disorders of Calcium Balance
Hypercalciuria
Calcium and or vitamin D deficiency
Inflammatory Disorders
Rheumatoid arthritis
Chronic Illness
Chronic kidney disease
Malignancies (eg, multiple myeloma, lymphoma, and leukemia)

Human immunodeficiency virus infection/acquired immunodeficiency syndrome
Organ transplant
Disuse/Immobility
Immobilization
Muscular dystrophy
Multiple sclerosis
Stroke/cerebrovascular accident
Genetic
Osteogenesis imperfecta
Cystic fibrosis
Hemochromatosis
Hypophosphatasia

Data from References 2, 4, 10–16.

TABLE 112-3

Select Medications Associated with Increased Bone Loss and/or Fracture Risk

Medications	Comments
Antiseizure therapy (phenytoin, carbamazepine, phenobarbital, and valproic acid)	↓ BMD and ↑ fracture risk; increased vitamin D metabolism leading to low 25(OH) vitamin D concentrations
Aromatase inhibitors (eg, letrozole and anastrozole)	↓ BMD and ↑ fracture risk; reduced estrogen concentrations
Calcineurin inhibitors (eg, cyclosporine and tacrolimus)	↓ BMD and ↑ fracture risk; increase osteoclast activity
Glucocorticoids (long-term oral therapy)	↓ BMD and ↑ fracture risk; increased bone resorption and decreased bone formation, and decreased calcium absorption and reabsorption; dose and duration dependent; see “Special Populations” section
Gonadotropin-releasing hormone agonists (eg, leuprolide and goserelin) or analogs (ganirelix)	↓ BMD and ↑ fracture risk; decreased sex hormone production
Heparin (unfractionated, UFH) or low molecular weight heparin (LMWH)	↓ BMD and ↑ fracture risk (UFH >>> LMWH) with long-term use (eg, >6 months); decreased osteoblast replication and increased osteoclast function
Loop diuretics (eg, furosemide)	↑ fracture risk; increased calcium renal elimination
Medroxyprogesterone acetate depot administration	↓ BMD, fracture risk unknown; possible BMD recovery with discontinuation; decreased estrogen concentrations
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) (tenofovir disoproxil fumarate > other NRTIs)	↓ BMD, fracture risk unknown; greater risk when combined with pharmacological boosters
Proton pump inhibitor therapy (long-term therapy)	↓ BMD and ↑ fracture risk; possible calcium malabsorption secondary to acid suppression for calcium carbonate salts
Selective serotonin reuptake inhibitors	↓ BMD and ↑ fracture risk; decreased osteoblast activity
Sodium glucose cotransporter 2 (SGLT2) inhibitors (canagliflozin; class effect uncertain)	↓ BMD and ↑ fracture risk; alteration in calcium and phosphate homeostasis; increased bone resorption
Thiazolidinediones (pioglitazone and rosiglitazone)	↓ BMD and ↑ fracture risk; decreased osteoblast function
Thyroid—excessive supplementation	↓ BMD and ↑ fracture risk associated with suppressed serum TSH; possible increase in bone resorption
Vitamin A—excessive chronic intake (>10,000 units of retinol form)	↓ BMD and ↑ fracture risk; decreased osteoblast activity and increased osteoclast activity

BMD, bone mineral density; TSH, thyroid-stimulating hormone.

Data from References 2, 14, 17–22

Bone remodeling is a dynamic process that occurs continuously throughout life (see Fig. 112-2A-C).[14,17] One to two million tiny sections of bone are in the process of remodeling at any given time. Within these sections, the bone remodeling activities of bone resorption and bone formation are coupled and balanced. Bone remodeling is triggered to repair microdamage to the skeleton and serves to support calcium homeostasis by maintaining a normal serum calcium, releasing calcium from the bone into the blood stream as needed. Within an active bone remodeling unit, osteoclasts (bone resorbing cells) work to resorb bone during the resorptive phase, then this process reverses and osteoblasts (bone-forming cells) work to form bone during the formation phase. Osteoblasts then become incorporated into the bone matrix as osteocytes or cover the surface as lining cells, both with bone-communication activities. The unit then becomes inactive and enters a quiescent phase. If remodeling becomes unbalanced and bone resorption surpasses bone formation or if the phases become uncoupled and bone resorption occurs without adequate formation, a decrease in BMD results. Osteocytes and lining cells play key roles in the process and can trigger a new remodeling cycle.

Three schemas show the overview and molecular level details of the bone remodeling cycle. The three schemas show the overview and molecular level details of the bone remodeling cycle. Schema (A) on the top gives the overview of remodeling process with the six steps involved in bone remodeling: Step 1 = initiation, Step 2 and 3 = resorption, Step 4 =reversal, Step 5 = formation, and Step 6 = quiescence. The schema (B) in the middle gives the molecular level detail of major pathways during bone resorption (mainly steps 2 and 3). The schema (C) at the bottom gives the molecular level detail of major pathways during bone formation (mainly steps 4 and 5) Hence, steps 2 to 5 are also points of osteoporosis medication targets. A mature osteoclast is formed from hematopoietic stem cell under the action of receptor activator of nuclear factor kappa β ligand (RANKL), interleukins 1 and 6 (IL-1, IL-6), macrophage colony stimulating factor (m-CSF), parathyroid hormone (PTH), parathyroid-releasing protein (PTHrP), 1,25(OH) vitamin D, tissue growth factor-β (TGF-β), prostaglandin E2 (PGE_2), insulin-like growth factor (IGF), sclerostin, integrins, platelet-derived growth factor, bone morphometric proteins (BMP), fibroblast growth factor (FGF), and tumor necrosis factor-α (TNF-α).

The signaling of the bone remodeling cycle through the steps from resorption through quiescence is highly complex.[14,17] Many cytokines, growth factors, and hormones influence each step. The complete physiology of bone remodeling is not fully known but appears to begin with signals from lining cells or osteocytes that are triggered by stress, microfractures, biofeedback systems responsive to cytokines and growth factors and potentially certain diseases and medications (see Fig. 112-2B, step 1). A major stimulus for hematopoietic stem cell differentiation to become mature osteoclasts is the receptor activator of nuclear factor kappa β ligand (RANKL), which is a cytokine emitted from osteoblasts or osteocytes in step 2. IL-1, IL-6, m-CSF, PTH through RUNX2/cbfa1, PTHrP, 1,25(OH) vitamin D, TGF-β, PGE_2 IGF, sclerostin, and TNF-α stimulate RANKL release whereas estrogen and calcitonin inhibit RANKL release. RUNX2/cbfa1 also inhibit osteoprotegerin. The RANKL then binds to the receptor activator of nuclear factor kappa β (RANK) on the surface of osteoclast precursors initiating differentiation. The RANKL also stimulates mature osteoclast activation and bone adherence via $\alpha_v\beta_3$ integrins to resorb bone (step 3). This step is influenced by TGF-β, IGF 1 and 2, platelet-derived growth factor, BMP, and FGF. After bone attachment, the osteoclasts secrete hydrogen and chloride ions and proteinases, such as cathepsin K, collagenase, gelatinase, tartrate-resistant acid phosphate isoenzyme 5 (TRACP5b), and matrix metalloproteases (MMP) to dissolve the mineralized bone. Hydrogen ion production is under nonreceptor tyrosine kinase (Src) control, which needs to be bound to other compounds such as E3 ubiquitin ligase (Cbl), focal adhesion kinase (FAK), and phosphatidylinositol 3-kinase (Pl3K).

After bone is resorbed and a cavity is created, osteoclasts produce cytokines and growth factors to elicit osteoblast differentiation from mesenchymal stem cells, maturation, and activity (step 4).[14,17] Osteoblast differentiation can be inhibited by PPARγ, which directs mesenchymal cell maturation to adipocytes instead of osteoblasts. However, leptin produced by adipocytes can stimulate bone formation. Mature osteoblasts and osteocytes produce osteoprotegerin (OPG) that binds to RANKL, thereby stopping bone resorption. Leucine-rich repeat-containing G protein (LGR4) also binds RANKL and stops resorption.

The process of bone formation is complicated (see Fig. 112-2C).[14,17] First, wingless tail ligands (Wnt) bind to low-density lipoprotein receptor–related protein 5 or 6 (LRP5/6) and a frizzled coreceptor. Wnt binding is influenced by PTH and PTHrP, which fit into the same receptor PTH1R, IGF-1, and irisin, which is increased during exercise. Next, LRP5/6 binds to disheveled cytoplasmic protein (DSH), which then binds to axin. Axin now cannot bind to glycogen synthase kinase-3β (GSK-3β); thereby preventing degradation of β-catenin by casein kinase 1α (Csk1α) (step 5). Irisin also increases β-catenin. Accumulated β-catenin then enters the nucleus and binds to T-cell-specific transcription factor 4/lymphoid enhancer factor 1 (TCF/LEF). This complex signals target genes to create proteins to fill the resorption cavity with osteoid. Growth hormone and IGF-1 also increase bone collagen production. Next mineralization of bone with calcium, magnesium, and phosphorus follows to give the new matrix strength.

Once the cavity is mineralized, bone formation can be stopped through multiple signaling processes.[14,17] Secreted frizzled-related proteins (sFRP) or Wnt inhibitory factor 1 (WIF1) can bind to Wnt, preventing it from binding to LRP 5/6. Both sclerostin and Dickkopf-1 (Dkk-1 or Kremen) are secreted from osteocytes and bind to LRP5/6, which also prevents Wnt from binding with LRP 5/6. Axin can then bind to adenomatous polyposis coli (APC), Csk1α, and GSK-3β, which then can cause β-catenin degradation, osteoblast apoptosis, and the end of osteoblastic activity (step 6). The mature osteoblasts can become lining cells or osteocytes.

Quiescence is the phase when bone is at rest until another remodeling cycle is initiated.[14,17] Later, osteocytes can trigger initiation of a new remodeling cycle through secretion of sclerostin or RANKL to stimulate osteoclasts and bone resorption.

Hormones can influence the remodeling steps. Estrogen has many positive effects on the bone remodeling process in people of both genders. Most of estrogen's actions help to maintain a normal bone resorption rate.[26] Estrogen suppresses the proliferation and differentiation of osteoclasts and increases osteoclast apoptosis. Estrogen decreases the production of several cytokines that are potent stimulators of osteoclasts, including IL-6, IL-7, IL-17, TNF-α, and m-CSF, and increases IL-4, IL-10, TGF-β, and TGF-α, which increases osteoclast apoptosis. Estrogen also decreases RANKL and increases OPG to reduce osteoclastogenesis.

Most of testosterone's bone effects relate to its metabolism to estradiol and the above estrogen bone effects; however, testosterone does have some direct and indirect effects on osteoblasts.[13,27] Testosterone increases osteoblast proliferation and differentiation directly via the androgen receptor, and indirectly by increasing TGF-β, IGF-2, and decreasing IL-6 stimulation of osteoclasts. Testosterone also increases muscle strength, which can decrease falls leading to fractures. Leydig cells secrete insulin-like factor 3 (INSL3) that stimulates relaxin family peptide receptor 2 (RXFP2) thereby increasing osteoblast and osteocyte functions.[13] A 25-hydroxylase is also secreted that increases vitamin D metabolism to 25(OH) vitamin D.

Bone physiology has many genomic and genetic influences; isolating one or a few genes for correction will unlikely resolve the problems in an aging population for whom osteoporosis is a common problem.[16] Genetic mutations do result in bone disorders such as osteoporosis, osteogenesis imperfecta, and juvenile idiopathic osteoporosis. Heredity is important since family history, especially of a hip fracture in a parent, is a strong risk factor for osteoporosis development and fracture.

At least 56 loci have been identified that influence BMD and 14 loci for fracture risk, ranging from impacts on bone resorption (RANKL, OPG) to formation (Wnt, LRP5, and sclerostin).[28,29] Calcium, vitamin D, and estrogen receptors are also under genetic influence. Studies are conflicting as to whether an association exists between response to currently available antifracture medications and genetic profiles. Genetic modulation is in its infancy for osteoporosis prevention and treatment, but epigenomics and gene editing might lead to the creation of new medications and/or the ability to tailor medication choices to an individual's genetic profile.[29]

Calcium Homeostasis, Vitamin D, and Parathyroid Hormone

2 Calcium homeostasis is maintained by vitamin D and PTH, which influence calcium gastrointestinal (GI) absorption and renal reabsorption. Calcium absorption under normal conditions is approximately 30% and is improved with vitamin D sufficiency.[30,31] Calcium absorption is lower in the winter due to decreased exposure to required ultraviolet light that converts cholesterol in the skin to vitamin D. Absorption is reported to be higher in obesity, which is associated with greater vitamin D storage. Calcium absorption is predominantly an active rate-limited process in the duodenum and jejunum, which is controlled by many hormones, such as 1,25-dihydroxyvitamin D (1,25[OH] vitamin D), estrogen, and transient receptor potential cation channel subfamily V member 6 (TRPV6). A calcium transporter (calmodulin or calbindin) is required to bring calcium from the gut into the tissue wall and then across the enterocyte. Calcium is extruded into the circulation via calcium (Ca^{++}) adenosine triphosphatase (ATPase) and the sodium-calcium exchanger. Throughout the intestine, paracellular passive calcium diffusion occurs. This diffusion accounts for less than 15% of absorbed calcium, is not rate limited, and possibility is sensitive to 1,25(OH) vitamin D. Solvent drag plays a minor role in calcium absorption.

When the calcium-sensing receptor on parathyroid cells detects low serum calcium, PTH production increases. PTH then directly (minimal effect) and indirectly (predominant effect via increasing calcitriol production) causes calcium reabsorption by the kidney.[30,32] Calcium reabsorption increases as 25(OH) vitamin D concentrations increase, plateauing around 10 to 15 ng/mL (mcg/L; 25-37 nmol/L). Loop diuretics decrease, and thiazide diuretics increase calcium resorption in the kidney.

Sometimes, the increased fractional calcium absorption is insufficient to maintain normal serum calcium, requiring bone resorption for correction.[30,31] Consistent and high concentrations of PTH and calcitriol increase RANKL and decrease OPG, resulting in increased osteoclast activity, which releases calcium from bone to restore calcium homeostasis. Of note, low PTH concentrations for a short time (eg, teriparatide) increase bone formation.

Active 1,25(OH) vitamin D concentrations depend on skin conversion, dietary and supplemental intake, and PTH control.[30,32] The sun's ultraviolet B rays convert 7-dehydrocholesterol in the skin to cholecalciferol (vitamin D_3), which is the most abundant vitamin D source. A few foods contain ergocalciferol (vitamin D_2). Supplements and multivitamins contain cholecalciferol or ergocalciferol. Subsequent conversion of cholecalciferol and ergocalciferol to 25-hydroxyvitamin D (25[OH] vitamin D; calcidiol) occurs in the liver, and then, PTH stimulates conversion of 25(OH) vitamin D via 25(OH) vitamin D-1α-hydroxylase (CYP27B1) to its final active form, 1,25-dihydroxyvitamin D (calcitriol; 1,25[OH] vitamin D), in the kidney. Calcitriol binds to the intestinal vitamin D receptor (VDR) and then increases the action of calcium-binding proteins calmodulin and calbindin. As a result, the intestinal absorption of calcium and phosphorus is increased. The feedback system is completed with CYP27B1 activity inhibited by adequate calcium and phosphorus, and FGF23 inhibiting PTH synthesis.

Postmenopausal Osteoporosis

2 Estrogen deficiency causes significant bone density loss and compromises bone architecture.[4,26,66] Estrogen deficiency increases proliferation, differentiation, and activation of new osteoclasts and prolongs survival of mature osteoclasts. Interleukins 7 and 17, TNF-α, and interferon γ increase and TGF-β decreases resulting in more RANKL and less OPG. Loss of estrogen also increases calcium excretion and decreases calcium gut absorption through decreases in TRPV6 activity and 1,25(OH) vitamin D binding proteins. Estrogen deficiency can also be seen in other settings such as anorexia nervosa and lactation, and from medications, such as prolonged depot medroxyprogesterone acetate implants, aromatase inhibitors, and gonadotropin releasing hormone agonists.

Accelerated bone loss of both mass and strength begins during perimenopause (1-5 years premenopause) and continues up to 10 years after menopause due to increased bone resorption that exceeds bone formation.[2] During this time, increased bone loss can be as high as 2% per year, with total BMD loss due to menopause about 10% to 12%.[4] About 30% of peak bone mass is lost by the age of 80 years. Bone strength decreases by about 2.5% per year.[9] The number of remodeling sites increases, and resorption pits are deeper and inadequately filled by normal osteoblastic function. During menopause, trabecular bone is most susceptible, leading predominantly to vertebral and wrist fractures. Initially, women with early menopause (ie, before the age of 40 years) due to natural or induced causes have lower BMD than matched premenopausal women. After the age of 70 years, risk for fractures and low bone density becomes the same between the groups.

Male Osteoporosis

② Men lose about 0.8% of bone mass per year after the age of 60 years and 20% experience hypogonadism in their older adult years.[12] Men are at a lower risk for developing osteoporosis and osteoporotic fractures because of larger bone size, greater peak bone mass and connectivity, increase in bone width with aging, fewer falls, and shorter life expectancy. With aging, sex hormone binding globulin increases, which results in less free testosterone and thereby less testosterone available for conversion to estrogen. Estrogen inhibits bone resorption in men; however, androgen deficiency increases RANKL release and bone resorption. Mortality rate after a fracture is greater for men (19.5%) than women (12.5%).

Male osteoporosis results from aging or secondary causes (see Tables 112-2 and 112-3).[12,13,27] The most common risk factors for men are smoking, alcohol abuse, low body weight, weight loss, age, long-term glucocorticoid use, androgen deprivation therapy, and low testosterone concentrations. Medical conditions and medications that cause hypogonadism can increase bone loss. Although many causes and serious fracture outcomes, osteoporosis is underdiagnosed in men.

Age-Related Osteoporosis

② Age-related bone mass and strength loss begin after peak bone mass is reached.[16] (Zhu) About 0.5%-1% of BMD is loss each year after the age of 30 years in males and until menopause for females.[4] Bone loss accelerates to 2% for 1 to 3 years before and 5 to 10 years post menopause before returning to normal aging bone loss.[4] After the age of 60 years, bone loss for both sexes is 1% to 1.5% per year.[8] Age-related osteoporosis occurs in older adults because of accelerated bone turnover rate and reduced osteoblast bone formation.[23,90] These bone changes occur from hormone deficiencies; calcium and vitamin D deficiencies due to changes in intake, absorption, and metabolism; decreased production or function of cytokines or other bone biochemicals; decreased molecular signaling; increase in redox status and free radical formation; increase in adipocytes; decreased body water; telomere shortening; and less exercise. Fracture risk for a given BMD value increases with aging.[8] For example, at a T-score of -2.5, a 50-year-old postmenopausal woman has about a 4% probability of a hip fracture, whereas a 70-year-old woman has about a 9% probability.[23] Hip fracture risk rises dramatically in older adults because of the cumulative loss of cortical and trabecular bone and an increased risk for falls.

Sarcopenia increases with aging with risk factors similar to osteoporosis.[14] The decrease in muscle strength and function results in weakness and balance instability leading to a greater likelihood of falls and fractures. Falls accounted for 87% of fractures in older adults.

Illness-Induced Secondary Causes of Osteoporosis

①② A secondary medical cause of osteoporosis is common (see Table 112-2). Symptoms, laboratory test results, certain diseases and medications, and/or a decreased Z-score from a DXA can suggest a secondary cause, warranting a more comprehensive work-up.

Medication-Induced Secondary Causes of Osteoporosis

①③ Medication-related reductions in BMD and associated fractures are a common secondary cause of osteoporosis.) Table 112-3 lists select medications associated with bone loss and/or fracture risk as well as the proposed mechanisms of bone loss.[18–22] Alternative medications should be used when possible, with consideration given to patients' individual risk and baseline BMD status. When these medications cannot be avoided, periodic re-assessment of benefits and risks should be performed, as reversal of bone loss might be possible upon discontinuation of some of these medications. Two of the most common causes of medication-induced osteoporosis, glucocorticoids, and certain cancer chemotherapies are discussed later in this chapter.

CLINICAL PRESENTATION

Table 112-4 outlines the clinical presentation of osteoporosis Osteoporosis is a silent disease, frequently not detected until a fracture is experienced or noticed on x-ray. Many vertebral fractures are asymptomatic, with patients sometimes attributing mild back pain to other factors, such as advanced age or work. Some new vertebral fractures present with moderate-to-severe back pain that can radiate down the leg. The pain usually subsides after 2 to 4 weeks; however, residual chronic back pain can persist. Multiple vertebral fractures decrease height and sometimes curve the spine (kyphosis or lordosis). Patients with a nonvertebral fracture frequently present with severe pain, swelling, and reduced function and mobility at the fracture site.

TABLE 112-4

Clinical Presentation of Osteoporosis

General

- Many patients are unaware they have osteoporosis until testing or fracture.
- Fractures can occur after bending, lifting, or falling, or independent of any activity.

Symptoms

- Frequently asymptomatic
- Pain
- Immobility
- Depression, fear, and low self-esteem from physical limitations and deformities

Signs

- Shortened stature (>1.5 in. [4 cm] loss from maximum height; >0.8 in. [2 cm] loss in 1 year), kyphosis, or lordosis
- Fragility (low-trauma) vertebral, hip, wrist, or forearm fracture

Laboratory tests

- Routine tests: comprehensive metabolic profile (creatinine, calcium, phosphorous, electrolytes, alkaline phosphatase, and albumin), 25(OH) vitamin D, thyroid-stimulating hormone, complete blood count, total testosterone (for men), and 24-hour urine calcium and creatinine concentrations
- Bone turnover markers (eg, serum NTX, serum CTX, and serum PINP) are sometimes used, especially to determine if high bone turnover exists
- Additional testing if the patient's history, physical examination, or initial laboratory and or diagnostic tests suggest a specific secondary cause (eg, intact parathyroid hormone, free testosterone, serum parathyroid, and celiac panel)

Other diagnostic tests

- Spine and hip bone density measurement using central dual-energy x-ray absorptiometry (DXA)
- Vertebral fracture assessment (VFA) with DXA technology
- Radiograph ordered for other reasons that shows low bone density
- Radiograph to confirm fracture
- Balance and mobility tests

CTX, C-terminal crosslinking telopeptide of type 1 collagen; NTX, N-terminal crosslinking telopeptide of type 1 collagen; PINP, procollagen type 1 N-terminal propeptide.

Data from References 2, 4, 6, 10, 21, 33, 34.

Consequences of Osteoporosis

Osteoporosis can lead to fragility/low-trauma fractures defined as fracture that occurs as a result of a fall from standing height or less or with minimal to no trauma.[2] Fractures of the vertebrae, hip, forearm, and humerus are considered major osteoporotic fractures whereas other fractures are generally not considered osteoporosis-related. Osteoporotic fractures can lead to increased morbidity and mortality and decreased quality of life. Pain and physical deformity are common, and these changes can lead to other health consequences.[4] For example, severe kyphosis can lead to respiratory problems as a result of compression of the thoracic region and GI complications such as poor nutrition from intra-abdominal compression.

Depression is common because of fear of falling/fracture, pain, loss of self-esteem from physical deformity, and loss of independence and mobility after fracture.

Hip fractures are associated with the greatest increase in morbidity and mortality. After a hip fracture, 40% of patients have mobility limitations, 50% no longer can live independently or require long-term care (25%), and about 12% to 20% die within the year from complications of the hip fracture or other comorbid disease processes.[2,8] Men have a higher 1-year mortality rate after hip fracture than women.[12] People of color have greater morbidity and mortality after a fracture than non-Hispanic White people.[3]

Wrist fractures occur more commonly in younger postmenopausal women and are frequently a result of a fall on an outstretched hand. Although they cause less disability than other fracture sites, negative outcomes include prolonged pain and weakness, and difficulty with activities such as meal preparation, using a keyboard, and lifting at work.

Once a low-trauma fracture has occurred, the risk for subsequent fractures goes up exponentially.[8] Vertebral fractures, even if asymptomatic, are a major predictor of a future fracture with up to a five- to seven-fold increase in future vertebral fractures and an increased risk at other sites.[4] Patients with a hip fracture have a 2% to 10% chance of a second hip fracture.[4]

Patient Assessment

Laboratory tests and other assessments are described in Table 112-4. Height should be measured annually using a wall-mounted stadiometer. Low bone density (sometimes called osteopenia) reported on routine radiographs is a sign of significant bone loss and requires further evaluation for osteoporosis. Additional tests will be required that are specific to potential secondary causes (Tables 112-2 and 112-3). In addition to physical examination and laboratory tests, patients can be assessed with risk factor assessment tools, osteoporosis quality of life questionnaires, peripheral and central DXA, ultrasonography, and bone turnover markers (BTM).

Risk Factor Assessment

The aim of an initial osteoporosis risk assessment screening is to identify those patients who are at risk for osteoporosis and osteoporotic fractures (see Table 112-1) and/or would benefit from further evaluation or pharmacologic intervention. The most commonly used assessment is the fracture risk assessment (FRAX) tool[2]; the Garvan tool[35] is another option.

④ The FRAX tool was created to be used for screening and diagnosis.[2] It can be used without DXA results, however, estimates improve when T-scores are available. This tool uses 11 risk factors: age, race/ethnicity, sex, previous fracture, parent history of hip fracture, body mass index, glucocorticoid use (current use or past use for three or more months of the equivalent of at least 5 mg of prednisolone daily), current smoking, alcohol use of three or more drinks per day, rheumatoid arthritis, and select secondary causes of osteoporosis (see Table 112-1); with optional entry for femoral neck BMD (g/cm^2). The FRAX tool calculates an individual's percent probability of any major osteoporotic fracture and hip fracture in the next 10 years. Each country establishes cut-off points for fracture risk treatment decisions. For the United States, they are 20% or higher for major osteoporotic fracture and 3% or higher for hip fracture. Most guidelines use these universal cutoffs, but others are beginning to recommend age-adjusted FRAX cutoffs to prevent undertreatment of younger people and overtreatment of older people or create a middle zone in which BMD would be needed to determine treatment.[34] For example, for a 55-year-old person, a 10% 10-year risk of major osteoporotic fracture would be used, and for an 80-year-old person, 30% would be used. For postmenopausal women younger than 65 years, a 10-year major osteoporotic fracture risk of greater than 8.4% would result in a referral for a central DXA.[2,36] Some important risk factors for fracture, for example, falls, multiple fractures, recent fracture, or other common secondary causes, are not accommodated in the FRAX model.

The Garvan calculator uses four risk factors (age, sex, low-trauma fracture, and falls) with the option to also use BMD.[2,6,35] It calculates 5- and 10-year risk estimates of any osteoporotic/fragility fracture and hip fracture. This tool corrects some disadvantages of the FRAX tool since it includes falls and number of previous fractures, but it does not use as many other risk factors.

Screening Using Peripheral Bone Mineral Density Devices

Peripheral bone density devices that use DXA (pDXA) or quantitative ultrasonography (QUS) are helpful as screening tools to determine which patients require further evaluation with central DXA or for decision-making if central DXA testing is not available.[2,36,37] Peripheral DXA of the forearm, heel, or finger uses a low amount of radiation and requires personnel with special training. Quantitative ultrasonography at the heel and other peripheral sites uses sound waves without radiation, and specially trained personnel are not needed. The heel is the only skeletal site at which QUS has been validated.[37] The QUS has better fracture predictive value than pDXA and has demonstrated the ability to predict fractures in postmenopausal women and in men 65 years of age or older. The specific peripheral T-score threshold for referral is not universally defined and varies by device. These tests should not be used for diagnosis or for monitoring response to therapy.[37]

Peripheral devices are considerably less expensive than central DXA, easy to use, portable, fast (less than 5 minutes), and can predict general fracture risk. They are popular for screening patients at health fairs and community pharmacies. Patients already identified as being at high risk for osteoporosis based on risk factors, fragility fracture, or secondary causes for osteoporosis should be referred for central DXA testing.

Central Dual-Energy X-Ray Absorptiometry

④ BMD measurements at the hip or spine can be used to assess fracture risk, establish the diagnosis and severity of osteoporosis, and confirm osteoporosis following a low-trauma fracture.[2,34] Multiple techniques are available for measurement of BMD and include DXA, quantitative computed tomography (QCT), digital x-ray radiogrammetry, and radiographic absorptiometry. Central DXA is the most widely used technique and preferred for making therapeutic decisions.[37] It has high precision, short scan times, low-radiation dose (comparable to the average daily dose from natural background), and stable calibration. Measurements of lumbar spine, femoral neck, and total hip BMD are recommended with the lowest BMD value used for diagnosis. The forearm (distal third of the radius) can be used as an alternative if the preferred areas cannot be scanned.[2,4,34,37] Trabecular bone score (TBS) is a newer technology available on some densitometers that can provide measurements of bone quality and microarchitecture. Low TBS is independently associated with increased fractures and can be used in combination with BMD and FRAX scores to better identify those at increased fracture risk.

Several consensus guidelines and position statements are consistent in recommending central BMD testing for all women aged 65 years or older, men aged 70 years or older, postmenopausal women younger than 65 years and men 50 to 69 years old with risk factors for fracture, and patients with an identified secondary cause for bone loss.[2,4,12,37] The US Preventive Services Task Force (USPSTF) provides similar recommendations for screening in women 65 years or older and in women under the age of 65 years with additional risk factors as determined by a clinical risk assessment tool, such as FRAX.[36] This group, however, has concluded that current data are insufficient to make recommendations for screening in men. Patients with a fragility fracture do not need a DXA for an osteoporosis diagnosis, but the results are helpful for determining the severity of osteoporosis and as a baseline for monitoring response to therapy.[2] The DXA results can also help patients make decisions about the need for lifestyle changes and prescription osteoporosis medications. In the absence of a suspected or known secondary cause for osteoporosis or a history of a low-trauma fracture, central BMD testing is not recommended for children,[15] women,[38] or men younger than 50 years.[13]

A central DXA BMD report provides the actual bone density value (in g/cm^2), T-score, and Z-score.[37] The T-score is used for diagnosis and is a comparison of the patient's BMD to the mean BMD of a healthy, young (20-29 year olds), and sex-matched White reference population. It is not adjusted for age, race, or ethnicity. The T-score is the number of standard deviations from the mean of the reference population.[37] The Z-score is similar but compares the patient's BMD to the mean BMD for a healthy sex- and age-matched population. The patient's race and ethnicity should be used for the Z-score if available. The Z-score is sometimes helpful in determining whether a secondary cause for osteoporosis is present and is used for diagnosis (value ≤ −2.0) in children, premenopausal women, and men younger than 50 years. The actual bone density value is most useful for serial monitoring of therapy response; follow-up BMD is recommended every 1 to 3 years by some guidelines,[2,4] although other guidelines recommend every 5 years in postmenopausal women.[1,34] The DXA results after medication initiation need to be above the machine's least significant change to be clinically relevant. For patients with normal bone density or those in the upper range of low bone mass, time between follow-up scans can be lengthened. Most insurance carriers, including Medicare, cover BMD testing every 2 years.

Using the spine DXA image, a VFA can be performed to assess for vertebral fractures that might otherwise go undetected.[2,4,37] Each vertebra is visually evaluated for fracture and fractures are assessed for severity. This result becomes important for treatment decisions in patients with low bone mass. Because many vertebral fractures are asymptomatic, VFA is recommended for those at high risk of an undiagnosed vertebral fracture. This includes patients with a T-score less than −1.0 when one or more of the following criteria are also present: women aged at least 70 years or men aged at least 80 years; a historical height loss of more than 1.5 in. (4 cm); a self-reported but undocumented prior vertebral fracture; or patients on glucocorticoid therapy (≥5 mg prednisone or equivalent daily for 3 months or more).

Laboratory Tests

Routine laboratory testing (see Table 112-4) is used for initial bone health assessment.[2,4,10,12,15] To evaluate secondary causes, additional testing is conducted, which will be specific to the suspected secondary cause.

Bone Turnover Markers

BTM are commonly used in clinical trials and sometimes in clinical practice.[2,4] They can be used to assess bone pathophysiology, predict fracture risk, monitor response to osteoporosis medications, evaluate medication adherence, and determine the need for restarting bisphosphonates after a drug holiday. Although many BTMs exist, serum carboxyterminal propeptide of type-I collagen (PINP) and bone-specific alkaline phosphatase (BSAP) are the preferred bone formation markers, and serum C-terminal telopeptide type-1 collagen (CTX) is the preferred bone resorption marker. Response to osteoporosis therapy can be measured with BTMs as early as 2 to 3 months; however, monitoring is usually done 3 to 6 months after osteoporosis medication initiation. Goal values would be at or below median premenopausal concentrations for antiresorptive medications and significant increase for formation medications.[2] Circadian variability, seasonal variations, food intake, recent exercise, some diseases and conditions, and assay variability can affect results and decrease utility in clinical practice. Fasting morning samples should be obtained with repeat tests done at the same facility with the same assay to decrease interassay variability. Of note, fractures increase BTMs for a short time frame. These tests can be expensive with coverage varying by health insurance plan. As an alternative, bone-specific alkaline phosphatase can be used, which is usually covered.

Diagnosis of Osteoporosis

⑥ The diagnosis of osteoporosis is based on a low-trauma fracture or femoral neck, total hip and/or spine DXA using World Health Organization (WHO) T-score thresholds.[2] Low bone mass (preferred term) or osteopenia is a T-score between –1 and –2.5, and osteoporosis is a T-score at or below –2.5. Although these definitions are based on data from postmenopausal white women, they are also applied to perimenopausal women, men aged 50 years and older, and adults from different races and ethnicities. The diagnosis of osteoporosis in children,[15] premenopausal women,[11] and men under 50 years of age[13] should be based on a Z-score at or less than –2.0 in combination with other risk factors or fracture. Without a history of clinically significant fracture, children, premenopausal women, and men are given a diagnosis of bone mass below the expected range for age.

PREVENTION AND TREATMENT

Desired Outcomes

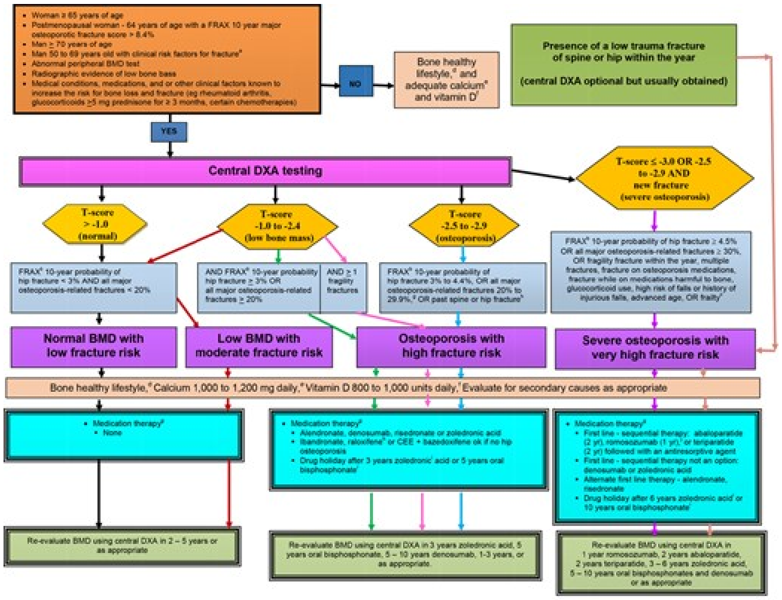
The primary goal of osteoporosis care should be prevention. Optimizing skeletal development and peak bone mass accrual in childhood, adolescence, and early adulthood will ultimately reduce the future incidence of osteoporosis. Once low bone mass or osteoporosis develops, the objective is to improve or stabilize bone mass and strength, and prevent fractures. In patients who have already suffered osteoporotic fractures, reducing pain and deformity, improving functional capacity, improving quality of life, and reducing future falls and fractures are the main goals.

General Approach to Prevention and Treatment

⑤⑥ A bone-healthy lifestyle should begin at birth and continue throughout life. The foundation of osteoporosis prevention and treatment is a bone-healthy lifestyle. Supplements and medications are used when lifestyle habits are insufficient or suboptimal, osteoporosis has developed, and/or a low-trauma fracture occurs. Guidelines and position statements recommend considering prescription therapy in any postmenopausal woman or man aged 50 years and older presenting with one of the following scenarios: a hip or vertebral fracture; T-score of −2.5 or lower at the femoral neck, total hip, or spine; or low bone mass (T-score between −1.0 and −2.5 at the femoral neck, total hip, or spine) with a FRAX 10-year probability of hip fracture of 3% or more or any major osteoporosis-related fracture of 20% or more. Figure 112-3 provides an osteoporosis management algorithm for postmenopausal women and men aged 50 years and older that incorporates both nonpharmacologic and pharmacologic approaches.

FIG. 112-3

[a] Major clinical risk factors for fracture: advanced age, current smoker, low body weight or body mass index, personal history of fracture as an adult (after age 50 years), history of osteoporosis/low trauma fracture in a first-degree relative, excessive alcohol intake.



Woman ≥ 65 years of age
Postmenopausal woman - 64 years of age with a FRAX 10 year major osteoporotic fracture score > 8.4%
Man ≥ 70 years of age
Man 50 to 69 years old with clinical risk factors for fracture[a]
Abnormal peripheral BMD test
Radiographic evidence of low bone base
Medical conditions, medications, and or other clinical factors known to increase the risk for bone loss and fracture (eg rheumatoid arthritis, glucocorticoids ≥5 mg prednisone for ≥ 3 months, certain chemotherapies)
NO
Bone healthy lifestyle,[d] and adequate calcium[e] and vitamin D[f]
Presence of a low trauma fracture of spine or hip within the year
(central DXA optional but usually obtained)
YES
Central DXA testing
T-score ≤ -3.0 OR -2.5 to -2.9 AND new fracture (severe osteoporosis)
T-score > -1.0 (normal)
T-score -1.0 to -2.4 (low bone mass)
T-score -2.5 to -2.9 (osteoporosis)
FRAX[b] 10-year probability of hip fracture < 3% AND all major osteoporosis-related fractures < 20%
AND FRAX[b] 10-year probability hip fracture ≥ 3% OR all major osteoporosis-related fractures ≥ 20%
AND ≥ 1 fragility fractures
FRAX[b] 10-year probability of hip fracture 3% to 4.4%, OR all major osteoporosis-related fractures 20% to 29.9%,[g] OR past spine or hip fracture[h]
FRAX[b] 10-year probability of hip fracture ≥ 4.5% OR all major osteoporosis-related fractures ≥ 30%, OR fragility fracture within the year, multiple fractures, fracture on osteoporosis medications, fracture while on medications harmful to bone, glucocorticoid use, high risk of falls or history of injurious falls, advanced age, OR frailty[i]
Normal BMD with low fracture risk
Low BMD with moderate fracture risk
Osteoporosis with high fracture risk
Severe osteoporosis with very high fracture risk
Bone healthy lifestyle,[d] Calcium 1,000 to 1,200 mg daily,[e] Vitamin D 800 to 1,000 units daily,[f] Evaluate for secondary causes as appropriate
Medication therapy[j]
None
Medication therapy[j]
Alendronate, denosumab, risedronate or zoledronic acid
Ibandronate, raloxifene[k] or CEE + bazedoxifene ok if no hip osteoporosis
Drug holiday after 3 years zoledronic[l] acid or 5 years oral bisphosphonate[l]
Medication therapy[j]
First line - sequential therapy: abaloparatide (2 yr), romosozumab (1 yr),[l] or teriparatide (2 yr) followed with an antiresorptive agent
First line - sequential therapy not an option: denosumab or zoledronic acid
Alternate first line therapy - alendronate, risedronate
Drug holiday after 6 years zoledronic acid[l] or 10 years oral bisphosphonate[l]
Re-evaluate BMD using central DXA in 2 – 5 years or as appropriate
Re-evaluate BMD using central DXA in 3 years zoledronic acid, 5 years oral bisphosphonate, 5 – 10 years denosumab, 1-3 years, or as appropriate.
Re-evaluate BMD using central DXA in 1 year romosozumab, 2 years abaloparatide, 2 years teriparatide, 3 – 6 years zoledronic acid, 5 – 10 years oral bisphosphonates and denosumab or as appropriate

Nonpharmacologic Therapy

(5) Nonpharmacologic therapy, referred to as a bone-healthy lifestyle, includes proper nutrition, moderation of alcohol intake, smoking cessation, exercise, and fall prevention. A bone-healthy lifestyle that is employed early in life will help to optimize peak bone mass, and if continued throughout life, it will minimize bone loss over time. A bone-healthy lifestyle not only maintains or increases BMD but it also helps decrease falls and fragility fractures.

Diet

(5) Overall, a diet well balanced in nutrients and minerals with limited salt, alcohol, and caffeine use are important for bone health. Adequate amounts of calcium and vitamin D have documented impacts on bone health. Protein is required for bone, thus the recommended dietary allowances (RDAs) of 0.8 g/kg body weight per day is recommended for adults increasing to 1 to 1.2 g/kg body weight in older adults and to 1.5 g/kg body weight for some chronic illnesses.[8] Magnesium, boron, and vitamin K have a physiologic role in bone development and maintenance but either no or insufficient data exist to establish them independently as supplemental agents for prevention and treatment of osteoporosis. Some of these agents are included in calcium combination products and are found in multivitamins. Strontium ranelate has documented positive bone effects and is marketed in Europe for prevention of osteoporosis.

Eating disorders are associated with increased bone loss and fractures.[11,15] Being thin or having anorexia nervosa are well known to decrease bone mass. In the past, obesity was thought protective due to increased estrogen production and stimulation of bone remodeling due to weight bearing; however, emerging literature suggests adipocytes have negative impacts on bone health.

Calcium

(5) (7) Adequate calcium intake is necessary for calcium homeostasis throughout life, bone development during growth, and bone maintenance thereafter. The Institute of Medicine (IOM) recommended calcium intakes are based on age and gender (Table 112-5).[2,34,39] These values represent the average daily amount needed to meet requirements for 97% to 98% of healthy people. Higher intakes might be needed when concomitant diseases and medications known to negatively affect calcium and vitamin D homeostasis exist. Ingesting calcium-containing and/or calcium-fortified foods and

beverages is the preferred method to achieve daily calcium requirements. Dairy products generally have the highest amount of calcium per serving and are available in low-fat options. Some food sources result in good calcium absorption but have low elemental calcium content (eg, broccoli). Carbohydrates increase calcium absorption whereas phylates (eg, beans, seeds, wheat bran) and oxalates (eg, spinach and rhubarb) decrease absorption.[6,35]

TABLE 112-5

Calcium and Vitamin D Recommended Dietary Allowances (RDAs) and Tolerable Upper Intake Levels (ULs)

Group and Ages	Elemental Calcium RDA (mg)	Calcium Tolerable Upper Intake Level (mg)	Vitamin D RDA (units)[a]	Vitamin D Tolerable Upper Intake Level (units)
Infants				
Birth to 6 months	200[b]	1,000	400[b]	1,000
7-12 months	260[b]	1,500	400[b]	1,500
Children				
1-3 years	700	2,500	600	2,500
4-8 years	1,000	2,500	600	3,000
9-18 years	1,300	3,000	600	4,000
Adults				
19-50 years	1,000	2,500	600[b,c]	4,000
51-70 years (men)	1,000	2,000	600[b,c]	4,000
51-70 years (women)	1,200	2,000	600[b,c]	4,000
>70 years	1,200	2,000	800[b,c]	4,000

[a] Some guidelines recommend intake to achieve a 25(OH) vitamin D concentration of >30 ng/mL (mcg/L; 75 nmol/L),[1,3,8] which is higher than the Institute of Medicine goal of >20 ng/mL (mcg/L; 50 nmol/L).[40]

[b] Adequate intake (evidence insufficient to determine an RDA).

[c] Guidelines recommend 800-1,000 units[1] or 1,000-2,000 units[3,8] for adults with osteoporosis.

Data from References 2, 34, 39.

People should be encouraged to evaluate their food and beverage intake to determine if they are receiving adequate amounts of calcium. To calculate the amount of calcium in a serving of food, consumers can add a zero to the percent of the daily value listed on food labels. For example, a serving of milk (8 oz. [~240 mL]) has 30% of the daily value of calcium. This translates to 300-mg calcium per serving. Websites can be used to identify foods and beverages high in calcium.[31]

Although many foods and beverages are high in calcium, the average daily dietary calcium intake is insufficient in many children and adults.[31] In addition, lactose intolerance limits dietary calcium intake. The incidence in Asian Americans (15%-100%), Native Americans (79%), African Americans (75%), and Hispanic Americans (51%) are higher than in White Americans (21%).[41] Patients with lactose-intolerance have several options to increase dietary calcium intake, including products containing lactase (Lactaid®), lactose-reduced milk, lactose-free milk, calcium-fortified milk alternatives (eg, soy and almond milk), certain aged cheeses, or yogurt with active cultures along with other nondairy calcium-fortified products (eg, orange juice, breakfast cereals, and energy bars). Vegan diets sometimes have insufficient calcium intake, but products such as tofu, calcium-fortified milk alternatives, and juices can be used. When diet cannot be enhanced to achieve adequate intakes, calcium supplements will be required.

Vitamin D

⑤ ⑧ Table 112-5 also lists the IOM recommended adequate intakes for Vitamin D.[2,34,39] The three main sources of vitamin D are sunlight (conversion of 7-dehydrocholesterol to vitamin D3), diet, and supplements. Vitamin D3 comes from oily fish, eggs, and fortified dairy products. Vitamin D2 comes from fungi and eggs (chickens given vitamin D2 in their diet). Websites can be used to identify the few foods high in vitamin D.[42] To calculate the amount of vitamin D in a serving of food, consumers can multiply the percent daily value of vitamin D listed on the food label by 4 (eg, 20% vitamin D = 80 units).

The overall prevalence of hypovitaminosis D (<20 ng/mL [mcg/L; 50 nmol/L]) in American adults has been estimated at 29%; with higher prevalence ratios observed in those who are older than 60 years, from a minority, have lower education levels, obese, physically inactive, and/or current smokers.[43] Low vitamin D concentrations can result from insufficient intake, dietary fat malabsorption, decreased sun exposure, decreased skin production, and/or decreased liver and renal metabolism. Endogenous synthesis of vitamin D can be decreased by factors that affect exposure to or decrease skin penetration of ultraviolet B light rays. Sunscreen use, full body coverage with clothing (eg, women wearing veils and full-length dresses), and darkly pigmented skin can all decrease vitamin D production. Seasonal variations in vitamin D concentrations are also seen with nadirs in late winter and peaks in late summer. Because few foods are naturally high or fortified with vitamin D, most people, especially older adults, require supplementation to achieve IOM recommended adequate intakes.

Isoflavones

⑤ Phytoestrogens (isoflavones, lignans, and coumestans) are plant-derived compounds that possess weak estrogenic agonist and antagonist effects throughout the body. Isoflavones are found in soy products, lignans in seeds, berries, and grains, and coumestans in peas, beans, broccoli and alfalfa sprouts. Genistein and daidzein are biologically active isoflavones found in soybeans. Isoflavones, genistein, and daidzein are also available as single-agent or combination supplements. Isoflavones produce estrogenic activity and increase IGF-1. The evidence supporting a positive bone benefit from phytoestrogen intake is conflicting with most studies showing little or no effect. The effect is greater on trabecular bone. Doses and products studied are quite varied with potentially more BMD activity with higher doses. Spine but not hip BMD is increased in some studies when compared to placebo. Isoflavones from soy foods appear safe; however, more information is needed, especially in women with breast cancer and for isoflavone supplements versus food sources.[44]

Alcohol

③ Chronic and excessive but not moderate alcohol consumption is associated with an increased risk for osteoporosis and fractures.[2,45] Alcohol increases bone resorption by increasing RANKL and decreases bone formation by inhibiting Wnt signaling pathway and increasing oxidative stress that results in osteoblast apoptosis. Patients with alcohol-use disorder might also have poor nutrition, decreased calcium absorption, altered vitamin D metabolism, estrogen inhibition, decreased testosterone production, chronic liver disease, and balance impairments resulting in more falls and fractures. Typical recommendations for alcohol consumption should be suggested, which are not to exceed 2 drinks per day for women and 3 drinks per day for men.

Caffeine and Tea

⑤ Although results are conflicting, excessive caffeine consumption is associated with increased calcium excretion, increased rates of bone loss, and a modestly increased risk for fracture.[45] Greater negative effects are seen in women. Ideally, caffeine consumption should be limited to two servings or less per day. For those with greater intakes, the increased calcium excretion might be compensated by additional calcium intake. Chronic tea drinking might have a positive benefit on bone mass, but no fracture outcomes exist.

Smoking

⑤ Cigarette smoking is an independent risk factor for osteoporosis and is associated with increased relative risk for fracture at all sites.[46] The effect is dose- and duration-dependent, but even passive smoking shows adverse effects on BMD. The negative bone effects are associated with reduced intestinal calcium absorption, lower 25(OH) vitamin D concentrations possibly due to increased hepatic metabolism, an increase in bone resorption from a decrease in production and increase in metabolism of estradiol leading to an increase in RANKL and decrease in OPG, decrease in osteoblasts and bone formation secondary to increase in cortisol and dehydroepiandrosterone sulfate, and impairment of osteoid production and mineralization.[16,46] The detrimental effects of smoking on physical function and balance can contribute to an increased risk of falls. Per guidelines, counseling patients of all ages on smoking cessation can help to optimize peak bone mass, minimize bone loss, and ultimately reduce fracture risk;[2] however, few studies have explored these outcomes.[46]

Exercise

⑤ Physical activity or exercise is an important nonpharmacologic approach to preventing osteoporotic fractures. Exercise increases bone mechanical strain, especially in weaker bone, thus stimulating osteocytes leading to bone resorption and then new stronger bone formation.[9] Weight-bearing exercise inhibits myostatin, which increases muscle and bone mass and decreases fat mass, and sclerostin and Dickoff-1, which prevents them from stopping bone formation.[17] Irisin is increased by exercise leading to increased bone formation by stimulating runX2, LRP 5/6, and β–catenin. Exercise can decrease the risk of falls and fractures by stabilizing bone density and improving muscle strength, coordination, balance, and mobility.[2,14,16,47] Physical activity is especially important early in life since peak bone mass is gained at that time and lack of exercise during growth can lead to suboptimal loading/straining, decreased stimulation of bone deposition, and reduced peak bone mass.[9] Although bone mass might not increase, bone strength will increase in older adults. All people of any age who are medically fit should be encouraged to perform a moderate-intensity weight-bearing activity (eg, running), plyometric (eg, jumping, hopping, bounding),and resistance activity (eg, weight machines, free weights, or elastic bands). Walking, swimming, cycling, and yoga have less impact on osteogenics but are still important. People at risk of osteoporosis should participate in exercise, including weight-bearing activities, at least three to four times weekly for 30 to 40 minutes per session. Adult recommendations for exercise from the American Heart Association can be suggested, which are 150 minutes of moderate-intensity aerobic exercise weekly or 75 minutes of vigorous-intensity exercise per week, and moderate- to high-intensity muscle strengthening at least twice a week.[48]

Fall Prevention

⑤ Risk of falling increases with advanced age predominantly as a result of balance, gait, and mobility problems, poor vision, reduced muscle strength, impaired cognition, multiple medical conditions (eg, arrhythmias, postural hypotension, Alzheimer’s disease, and Parkinson disease), and polypharmacy (especially psychoactive, cardiovascular, diabetes, seizure, and pain medications).[2,24] The ability to adapt to falls also decreases with aging. Older adults are more likely to sustain a hip or pelvic fracture because they tend to fall backward or sideways instead of forward.

Because of the link between falls and fractures, all older adults should be asked at least annually if they have fallen. The US Centers for Disease Control and Prevention have created an assessment tool.[49] If an older adult scores 4 or more, a comprehensive falls assessment should be conducted. Many other assessment tools exist to evaluate falls.

Generally, intervention programs that are multifactorial have greater effects on decreasing falls, fractures, other injuries, and nursing home and hospital admissions than single interventions.[2,24,40,47,50] Medication profiles should be reviewed for any unnecessary medications that can affect cognition and balance, and potentially increase fall risk. Consideration should be given to deprescribing or substitution with safer medications. Although Vitamin D supplementation has been advocated to reduce falls and fractures in some guidelines, the most recent USPSTF recommendation states the evidence is inadequate to prescribe this therapy for fall and fracture prevention. Maintenance of a regular individualized exercise program, such as tai chi, resistance training, and strengthening, should be recommended to improve body strength, balance, and agility. Other recommendations include resolving heart rate/rhythm irregularities, low blood pressure, and vision and foot problems, and using proper footwear. A home environment safety assessment is helpful to identify environmental solutions to decrease falls.[24,40,51] External hip protectors are specialized undergarments designed to pad the area surrounding the hip, decreasing the force of impact from a sideways fall.[8] Conflicting results and poor adherence limit their use. Many patient education materials exist with the US Centers for Disease Control and Prevention older adult falls prevention program being an excellent resource for patients and providers.[40]

Vertebroplasty and Kyphoplasty

During vertebroplasty and kyphoplasty cement is injected into fractured vertebra(e) for patients with debilitating pain from vertebral compression fractures. Although used to stabilize damaged vertebrae, reduce pain, and decrease opioid intake, this therapy is decreasing based on results showing effects that are similar to sham interventions, being short-term, and having no major pain benefit, and or are associated with vertebral fracturing around the cement, cement leakage into the spinal column, and nerve damage (rare).[52] The AACE/ACE guideline lists vertebral augmentation as an uncertain therapy due to limited data, potential for adverse treatment outcomes, and lack of long-term effects.[2]

Pharmacologic Therapy

⑨ Because nonpharmacologic interventions alone are frequently insufficient to prevent or treat osteoporosis, medication therapy is often necessary. Osteoporosis medication effects on fracture risk and BMD (Table 112-6), dosing (Table 112-7), and adverse effects and monitoring (Table 112-8) are described. Medication use should be combined with a bone-healthy lifestyle. People of color were less likely to receive osteoporosis prescription medications;[3] thus, health disparities need to be resolved to provide osteoporosis prevention to all women and men.

TABLE 112-6

Fracture and Bone Mineral Density Effects of Osteoporosis Medications from Pivotal Fracture Trials[a] in Postmenopausal Women

Medication	Vertebral Fracture	Nonvertebral Fracture	Hip Fracture	% Change in Spine BMD[b]	% Change in Hip BMD[b,c]
Abaloparatide	86%↓	43%↓	↔	10.4%↑	4.3%↑
Bazedoxifene	35%-42%↓	↔[d]	↔	2.1-3.0%↑	0.5%↑
Bazedoxifene with conjugated equine estrogens	ND	ND	ND	0.24%-1.6%↑	0.2%-1.5%↑
Bisphosphonates	41%-70%↓	20%-38%↓[e]	28%-50%↓[f]	3.1%-6.0%↑	1.8%-4.0%↑
Calcitonin	33%↓	↔	↔	3%↑	↔
Denosumab	68%↓	20%↓	40%↓	9.2%↑	6.0%↑
Estrogen with or without a progestogen	33%- 40%↓	13%-27%↓	30%-50%↓	3.5%-7%↑[f]	1.7%-5%↑[g]
Raloxifene	30%-68%↓[h]	↔	↔	2.6%↑	2.1%↑
Romosozumab	73%↓	ND/19%↓[i]	ND/38%↓[i]	11.3%-13.7%[g]↑	4.1%-6.9%↑
Teriparatide	65%↓	53%↓	↔	8.6%-9.7%↑	3.5%↑

[a] Fracture reductions are relative risk reductions, no head to head fracture studies except for raloxifene and bazedoxifene. Data should only be used for relative between class comparisons. Clinical trials have different patient samples and study designs. Most pivotal fracture trials were of 3-year duration except for abaloparatide (2 years), romosozumab (1 year) and teriparatide (18 months) studies.

[b] Relative to placebo; may vary based on duration of therapy and timing relative to menopause.

[c] Total hip (alendronate, ibandronate, zoledronic acid, bazedoxifene, denosumab, estrogen, abaloparatide, teriparatide, romosozumab) or femoral neck (calcitonin, estrogen, risedronate, and raloxifene).

[d] 50% decreases in nonvertebral fractures in subgroup of high-risk postmenopausal women (very low BMD and or previous fractures).

[e] Risedronate and zoledronic acid only; nonvertebral fracture reductions with ibandronate were not significant.

[f] Alendronate, risedronate, and zoledronic acid only; hip fracture data not reported with ibandronate.

[g] Data obtained from nonpivotal fracture trials.

[h] Includes data from a pivotal bazedoxifene trial with raloxifene as one of the comparators.

[i] Second year results after 1 year of romosozumab followed by alendronate or denosumab for 1 year.

[j] Includes data from teriparatide versus romosozumab study.

%, percent; BMD, bone mineral density; ↓, decrease; ↑, increase; ↔, no significant change; ND, no data.

Data from References 1, 2, 4, 39, 53–56.

TABLE 112-7: **Dosing of Drugs for Osteoporosis**

Medication	Brand Name	Dose	Comments
Antiresorptive Medications—Nutritional Supplements			
Calcium	Various	Adequate daily intake*: IOM:* 200-1,200 mg/day, varies per age; see Table 112-5); supplement dose is the difference between required adequate intake and dietary intake. Immediate-release doses should be <500-600 mg.	Recommend food sources first to achieve goal intake. Available in different salts including carbonate and citrate, absorption of other salts not fully quantified. Different formulations including chewable, liquid, gummy, softgel, drink, and wafer; different combination products. Review package to determine number of units per serving size and desired amount of elemental calcium. Give calcium carbonate with meals to improve absorption.
Vitamin D D3 (cholecalciferol)	**Over the counter** - Tablets, 400,	Adequate daily intake: IOM: 400-800 units/day to achieve adequate intake (see Table 112-5); guidelines: 800-2,000 units orally daily; if low 25(OH)	Vegetarians and vegans need to read label to determine if the vitamin D source is plant-based.

D$_2$ (ergocalciferol)	1,000, and 2,000 units • Capsules, 400, 1,000, 2,000, 5,000, and 10,000 units • Gummies, 300, 500, and 1,000 units • Drops, 300, 400, 1,000, and 2,000 units/mL or drop • Solution, 400 and 5,000 units/mL • Spray, 1,000 and 5,000 units/spray • Creams and lotions, 500 and 1,000 units per ¼ teaspoonful Prescription • Capsule, 50,000 units • Solution, 8,000 units/mL	vitamin D concentrations, malabsorption, or altered metabolism higher doses (>2,000 units daily) might be required. Vitamin D deficiency: 5,000 units or higher daily preferred over 50,000 units orally once to twice weekly for 8-12 weeks; repeat as needed. Higher doses until therapeutic concentrations reached.	Slight advantage of D3 over D2 for increasing serum 25(OH) vitamin D concentrations. For drops, make sure measurement is correct for desired dose. Ability of sprays, lotions, and creams to resolve deficiencies or maintain adequate intakes is unknown.
Antiresorptive Prescription Medications			
Bisphosphonates			
Alendronate	Fosamax Fosamax Plus D Binosto (effervescent tablet)	Treatment: 10 mg orally daily or 70 mg orally weekly Prevention: 5 mg orally daily or 35 mg orally weekly	Generic available, effervescent tablet is brand only. 70-mg dose is available as a tablet, effervescent tablet, solution, or combination tablet with 2,800 or 5,600 units of vitamin D3. Administered in the morning on an empty stomach with 6-8 ounces (180-240 mL) of plain water. Do not eat and remain upright for at least 30 minutes

			following administration. Do not coadminister with any other medication or supplements, including calcium and vitamin D. Caution if CrCl <35 mL/min (0.58 mL/s).
Ibandronate	Boniva	Treatment: 150 mg orally monthly, 3-mg intravenous quarterly Prevention: 150 mg orally monthly	Generics available. Administration instructions same as alendronate, except must delay eating and remain upright for at least 60 minutes. Caution if CrCl <30 mL/min (0.50 mL/s).
Risedronate	Actonel Atelvia (delayed-release)	Treatment and prevention: 5 mg orally daily, 35 mg orally weekly, 150 mg orally monthly	Generics available. 35-mg dose is also available as a delayed-release product. Administration instructions same as for alendronate, except delayed-release product is taken immediately following breakfast with at least 120 mL (ounces) of plain water. Caution if CrCl <30 mL/min (0.50 mL/s).
Zoledronic acid	Reclast	Treatment: 5-mg intravenous infusion yearly Prevention: 5-mg intravenous infusion every 2 years	Generic available. Can premedicate with acetaminophen to decrease infusion reactions. Contraindicated if CrCl <35 mL/min (0.58 mL/s). Also marketed under the brand name Zometa (4 mg) with different dosing for oncology-related indications.
RANK Ligand Inhibitor			
Denosumab	Prolia	Treatment: 60-mg subcutaneously every 6 months	Administered by a healthcare practitioner. Correct hypocalcemia before administration. Also marketed under the brand name Xgeva (70 mg/mL) with different dosing for treatment of hypercalcemia of malignancy, multiple myeloma, bone metastases from solid tumors, and giant cell tumor of bone.
Estrogen Agonist/Antagonist and Tissue Selective Estrogen Complex			

Raloxifene	Evista	60 mg daily	Generic available.
Bazedoxifene with conjugated equine estrogens (CEE)	Duavee	20 mg plus 0.45 mg CEE daily	For postmenopausal women with a uterus; no progestogen needed. Bazedoxifene monotherapy available in some countries.
Calcitonin			
Calcitonin (salmon)	Fortical	200 units (1 spray) intranasally daily, alternating nares every other day.	Nasal formulation only available as a generic. Refrigerate nasal spray until opened for daily use, then room temperature. Prime with first use. Also available as a subcutaneous injection.
Formation Medications			
Recombinant Human Parathyroid Hormone (PTH 1-34 units)			
Teriparatide	Forteo Bonsity	20-mcg subcutaneously daily	First dose sitting or lying. Refrigerate before and after each use. Use new needle with each dose. Inject in thigh or abdomen. Discard after 28 days or if cloudy. Forteo and Bonsity not interchangeable.
Human Parathyroid Hormone–Related Peptide (PTHrP[1-34]) Analog			
Abaloparatide	Tymlos	80-mcg subcutaneously daily for up to 2 years	First dose sitting or lying. Refrigerate before use then keep at room temperature. Use new needle with each dose. Inject in abdomen. Discard after 30 days.
Formation and Antiresorptive Medication			
Sclerostin Inhibitor			
Romosozumab	Evenity	210-mg subcutaneously monthly for 1 year; administered as two single use 105-mg/1.17-mL prefilled syringes	Correct hypocalcemia before administration. Refrigerate. Leave at room temperature for at least 30 minutes before use. Provider administration, exploring patient self-administration.

			Inject in abdomen, thigh, or upper arm; preferably each injection at a different site.

IOM, Institute of Medicine; NSAID, nonsteroidal anti-inflammatory drug.

TABLE 112-8

Medication Adverse Reactions and Monitoring

Medication	Adverse Reactions	Monitoring Parameters	Comments
Antiresorptive Medications—Nutritional Supplements			
Calcium	Constipation, gas, upset stomach, kidney stones	Dietary calcium intake, constipation	Education about a bowel healthy lifestyle (eg, adequate water, fiber, and exercise).
Vitamin D	Hypercalcemia, hypercalciuria, weakness, headache, somnolence, nausea. Rare: cardiac rhythm disturbance	Serum 25(OH) vitamin D concentration, symptoms	Adverse effects usually not experienced until 25(OH) vitamin D concentration more than 100-150 ng/mL (mcg/L; 250-375 nmol/L), which are generally not achieved with recommended therapeutic doses.
Antiresorptive Prescription Medications			
Bisphosphonates			
Bisphosphonates	Dyspepsia (oral), transient or chronic musculoskeletal pain, nausea, transient flu-like illness (injectable) Rare: GI perforation, ulceration, and/or bleeding (oral); osteonecrosis of the jaw; atypical femoral shaft fracture, severe musculoskeletal pain	Bone density, fractures, GI symptoms, muscle aches Serum calcium for zoledronic acid	Adherence is suboptimal, thus it should be assessed frequently. Assess correct use of product with refills. Risk outweighs benefit in pregnancy, use prior to or during pregnancy might cause fetal medication exposure.
RANK Ligand Inhibitor			
Denosumab	Back pain, arthralgia, eczema, dermatitis, and infection Rare: osteonecrosis of the jaw, atypical femoral shaft fracture	Bone density, fractures, serum calcium	REMS: Medication guide and monitoring plan due to risks of hypocalcemia, osteonecrosis of the jaw, atypical femoral shaft fractures, serious infections, and dermatologic adverse reactions. Contraindicated in pregnancy.

Estrogen Agonist/Antagonist and Tissue Selective Estrogen Complex			
Raloxifene	Hot flushes, leg pain, spasms, or cramps, peripheral edema, venous thromboembolism (warm swollen leg, chest pain, shortness of breath, coughing up blood, and change in vision)	Bone density, fractures, hot flushes, leg cramps, and blood clots	Contraindicated in pregnancy. Warning for fatal stroke; Rare events predominantly seen in women at high-risk for stroke.
Bazedoxifene with conjugated equine estrogens	Similar to raloxifene and estrogens	Bone density, fractures, leg cramps, blood clots	Contraindicated in pregnancy.
Calcitonin			
Calcitonin (salmon)	Rhinitis, epistaxis	Bone density, fractures, nasal irritation	Limited information regarding use in pregnancy.
Formation Prescription Medications			
Recombinant Human Parathyroid Hormone (PTH 1-34 units) Analog			
Teriparatide	Orthostasis with first few injections, pain at injection site, nausea, headache, dizziness, leg cramps, increase in uric acid, transient hypercalcemia, hypercalciuria	Bone density, fractures, trough serum calcium concentration 1 month after therapy initiation, urinary calcium if prior hypercalciuria or active urolithiasis	If serum calcium is high (>10.6 mg/dL [2.65 mmol/L]), calcium intake should be decreased. Warning about osteosarcoma in rats and therefore contraindicated in patients at high risk for this adverse event. In pregnancy, adverse events noted in animal studies. Not for use in pregnancy.
Human Parathyroid Hormone–Related Peptide [PTHrP(1-34)] Analog			
Abaloparatide	Orthostasis with first few injections, pain at injection site, headache, dizziness, leg cramps, increase in uric acid, hypercalcemia, hypercalciuria	Bone density, fractures, serum calcium concentration, urinary calcium if prior hypercalciuria or active urolithiasis	Warning about osteosarcoma in rats and therefore contraindicated in patients at high risk for this adverse event. Not for use in pregnancy.
Formation and Antiresorptive Prescription Medication			
Sclerostin inhibitor			

Romosozumab	Arthralgias, headache, muscle spasms, hypocalcemia, mild injection site pain, myocardial infarction, stroke, cardiovascular death. Antibody production with some neutralizing, an effect on efficacy or toxicity not reported. Rare: osteonecrosis of the jaw, atypical femoral fractures	Bone density, fractures, joint pain, injection site, serum calcium prior to and during therapy	Box warning about myocardial infarction, stroke, and cardiovascular death. Not for use in pregnancy.

REMS, risk evaluation and mitigation strategies.

Data from Reference 1; product prescribing labeling.

The North American Society guidelines for postmenopausal women, Endocrine Society guideline for postmenopausal women the American Association of Clinical Endocrinologists and American College of Endocrinology guideline for postmenopausal women, the American College of Physicians guideline for women and men, and the Bone Health and Osteoporosis Foundation guideline for women and men provide guidance on osteoporosis prevention and treatment strategies.[1,2,4,39]

Medication Treatments of First Choice

⑨ Alendronate, risedronate, zoledronic acid, and denosumab reduce both hip and vertebral fracture risks.[2] Abaloparatide, calcitonin, ibandronate, raloxifene, romosozumab, and teriparatide reduce vertebral but not hip fracture risks. Estrogen and testosterone therapies are not used for osteoporosis treatment, but when prescribed for other conditions will have a positive bone effect.[27] In theory, sequential therapy starting with bone formation medications and followed by antiresorption medications is recommended, especially in patients with osteoporosis and very high risk for fracture. Formation medication cost and injectable dosage forms limit sequential therapy as initial therapy. The algorithm (see Fig. 112-3) helps determine for whom medication therapy should be used. In general, prescription therapy combined with adequate intakes of calcium and vitamin D should be considered for any postmenopausal woman or man aged 50 years and older presenting with a fragility fracture, osteoporosis, or low bone mass combined with a FRAX 10-year probability of hip fracture of 3% or more or any major osteoporosis-related fracture of 20% or more. Type of fracture risk (spine, hip, or both) will also determine medication of choice. Calcitonin is a last-line therapy. The use of osteoporosis prescription medications in children,[10,15,57,58] premenopausal women,[11] and men younger than 50 years[12,13] occurs in special cases and is generally related to secondary medical and medication causes or genetic disorders.

Antiresorptive Therapies

Antiresorptive therapies include calcium, vitamin D, bisphosphonates, denosumab, estrogen agonists/antagonists (EAA), tissue selective estrogen complexes (TSEC), calcitonin, estrogen, and testosterone.

Calcium Supplementation

⑦ Calcium imbalance can result from inadequate dietary intake, decreased fractional calcium absorption, enhanced calcium excretion, and diseases and medications altering these processes. Adequate calcium intake (see Table 112-5) is considered a foundation for osteoporosis prevention and treatment in the guidelines and should be combined with vitamin D, especially when osteoporosis medications are taken.[2,34,39] If dietary intake cannot be increased to achieve adequate intake, calcium supplements can be used.

Efficacy

Calcium generally maintains BMD, although small BMD increases (0.6%-1.8%) have been documented.[2,59] These BMD effects are less than those observed with other osteoporosis medications. A USPSTF report states insufficient data exist to support using calcium and vitamin D supplementation to reduce fracture incidence.

Adverse Events

Calcium's most common adverse reaction, constipation, can first be treated with increased water intake, dietary fiber, and exercise. If still unresolved, smaller and more frequent calcium administration or a lower total daily dose can be tried. Calcium carbonate can create gas and cause upset stomach. Calcium citrate, a formulation with fewer GI side effects, is often recommended if calcium carbonate is not tolerated.

Calcium supplementation when combined with vitamin D can increase the risk of kidney stone formation. However, in some cases, calcium binds to oxalate in the gut, which decreases urinary oxalate excretion thereby decreasing kidney stones. Increased fluid intake and decreased salt intake might be warranted to prevent kidney stones. Calcium supplements resulting in total calcium intakes above the upper limit of intake can slightly increase coronary artery calcification and cardiovascular disease events.[1,31,60]

Interactions

Since calcium carbonate requires acid for disintegration, medications such as proton pump inhibitors and histamine type-2 receptor antagonists can decrease absorption from the carbonate product.[31] Fiber laxatives can also decrease the absorption of calcium if given concomitantly. Calcium can decrease the oral absorption of some medications including iron, tetracyclines, quinolones, bisphosphonates, and thyroid supplements.

Dosing and Administration

Many patients, especially those aged 60 years or older, do not ingest sufficient dietary calcium and therefore require supplements. To ensure adequate calcium absorption, 25(OH) vitamin D concentrations should be at least 10 to 15 ng/mL (mcg/L; 25-37 nmol/L). Because fractional calcium absorption is dose-limited, maximum single doses of 500 to 600 mg or less of elemental calcium are recommended.[2] Despite this, slow-release and/or absorbable calcium formulations (eg, Citracal Slow Release 1,200) are available in doses of 1,200 mg and advertised to be taken once daily. These high-dose products are sometimes two 600-mg tablets that can be taken at different times. Supplemental doses this high are usually not needed unless a severe dietary deficiency of calcium exists. Calcium carbonate is the salt of choice as it contains the highest amount of elemental calcium (40%) and is typically the least expensive. Calcium carbonate should be taken with meals, which increases gastric acidity resulting in product disintegration and dissolution. Calcium citrate (21% elemental calcium) has acid-independent absorption and does not need to be administered with meals. Although tricalcium phosphate contains 38% elemental calcium, calcium-phosphate complexes could limit overall calcium absorption. This product might be helpful in patients with hypophosphatemia that cannot be resolved with increased dietary intake.

Disintegration and dissolution rates vary significantly between products and lots. Products labeled United States Pharmacopeia “USP Verified” should be recommended. This indicates that the products have undergone the voluntary USP verification program, which ensures that the product contains the ingredients shown on the label at the stated strength/potency, and has been produced using safe, clean, and controlled manufacturing processes as specified by the USP and the US Food and Drug Administration (FDA). Products from unrefined oyster shell or coral calcium should not be recommended because of concerns for high concentrations of lead and other heavy metals. Some calcium products come in alternative dosage forms (eg, chewable tablets, dissolvable tablets, and liquid), which can be beneficial for select patients with issues such as swallowing large tablets. For all products, encourage patients to read the labeling carefully as the serving size is often more than just one tablet. In addition, product labeling sometimes recommends taking doses providing 1,000 to 1,200 mg/day, which often provides more calcium than needed to meet IOM requirements and could exceed tolerable upper limits when dietary calcium intake is adequate.

Some commercial calcium supplements contain other nutrients associated with bone physiology such as magnesium, vitamin K, “natural estrogens,” or isoflavones. Minimal BMD and no fracture data exist for these combination products. These products are also typically more expensive. Additionally, combining too many vitamins and supplements might exceed upper-tolerable nutrient limits and increase toxicities.

Vitamin D Supplementation

⑧ The IOM recommends adequate intakes of vitamin D from diet and/or supplementation for all ages (see Table 112-5). Current osteoporosis guidelines recommend slightly higher vitamin D maintenance doses (800-2,000 units daily).[2,34,38]

The desired therapeutic range for vitamin D is controversial. The IOM defines 20 ng/mL (50 nmol/L; 1 ng/mL = 2.5 nmol/L) as the cut point for normal 25(OH) vitamin D, below which a patient would be considered deficient. Current guidelines recommend treating patients with osteoporosis to a concentration of at least 20 ng/mL (mcg/L; 50 nmol/L) or 30 to 50 ng/mL (mcg/L; 75-125 nmol/L) 25(OH) vitamin D. Concentrations higher than 50 to 60 ng/mL (mcg/L; 125-150 nmol/L) can be associated with adverse effects.[2,38]

The major effects of vitamin D are achieved with 25(OH) vitamin D concentrations between 6 and 20 ng/mL (mcg/L; 15-50 nmol/L), including increasing calcium absorption (16 ng/mL [mcg/L; 40 nmol/L]) and decreasing BMD loss (up to 20 ng/mL [mcg/L; 50 nmol/L]).[61] Daily vitamin D doses of 500 to 700 units generally are sufficient to achieve vitamin D concentrations more than 20 ng/mL (mcg/L; 50 nmol/L), leading some experts to suggest the higher daily doses recommended in guidelines are not warranted. Other experts state not everyone achieves a 25(OH) vitamin D concentration greater than 30 ng/mL (mcg/L; 75 nmol/L), and therefore recommend 800 to 2,000 units daily, especially in adults at high risk or with osteoporosis. Furthermore, since most products are inexpensive and safe, the higher recommended doses are appropriate.[2,34,39] These higher recommendations are within the upper limit for vitamin D in adults, which is 4,000 units daily.

Serum 25(OH) vitamin D is the best indicator of total body vitamin D status.[42] Interassay variability exists; thus, the same laboratory should be used for repeat testing. Measurement of 25(OH) vitamin D concentration can be considered in anyone with high risk for low vitamin D, low bone density, history of a low-trauma fracture, frequent falls, unexplained muscle weakness, and/or bone pain.

Efficacy

Supplemental vitamin D given at doses of 700 to 800 units per day significantly reduces the incidence of both hip and nonvertebral fractures.[2] Small increases in BMD, improvement in muscle strength, and improvement in balance have also been observed. Several studies have analyzed the effect of supplemental vitamin D on falls; however, the USPSTF recommends against the use of supplemental vitamin D specifically for fall prevention.[24]

Interactions

Some medications can induce vitamin D metabolism including rifampin, phenytoin, barbiturates, valproic acid, and carbamazepine. Vitamin D absorption can be decreased by cholestyramine, colestipol, orlistat, and mineral oil. Vitamin D can enhance the absorption of aluminum; therefore aluminum-containing products should be avoided to prevent aluminum toxicity.

Dosing and Administration

Dosing of supplemental vitamin D should be based on IOM adequate intakes (see Table 112-5) or to achieve a 25(OH) vitamin D concentration of ≥30 ng/mL (mcg/L; 75 nmol/L), especially in those with osteoporosis.[2] Almost 30% of older adults have hypovitaminosis D (≤20 ng/mL [mcg/L; 50 nmol/L]), with higher prevalence in Black (72%) and Hispanic (43%) patients.[43,62] Replenishment doses will first be required in these patients before recommended maintenance doses.

Vitamin D can be taken as a single-agent or combination product. Supplements and multivitamins contain vitamin D3 or D2. Synthesized vitamin D3 can be made from irradiated sheep's wool and vitamin D2 from irradiated mushrooms. Guidelines suggest either product for prevention and treatment of vitamin D deficiency. Current guidelines recommend dosing with 5,000 units once daily for 8-12 weeks to achieve a target 25(OH) vitamin D concentration of ≥30 ng/mL (mcg/L; 75 nmol/L), followed by a maintenance dose of 1,000 to 2,000 units daily.[2,63] The preferred dosage form is vitamin D_3 (cholecalciferol).[2] Higher-dose prescription vitamin D regimens have less support[8] but are sometimes used,[63] especially when adherence and cost are concerns. An example regimen is 50,000 units given once weekly for 8 to 12 weeks, or until the 25(OH) vitamin D concentration reaches 30 ng/mL (mcg/L; 75 nmol/L), followed by 1,000 to 2,000 units daily to maintain this concentration. More than one multivitamin or large doses of cod liver oil daily are no longer advocated because of the risk of hypervitaminosis A, which can increase bone loss. Because the half-life of vitamin D is about 1 month, approximately 3 months of therapy are required before a new steady state is achieved and a repeat 25(OH)-vitamin D concentration should be obtained to assess efficacy of therapy.

Individuals with deficient concentrations of vitamin D are at risk for osteomalacia, a condition that can be mistaken for osteoporosis, which is characterized by decreased mineralization or "softening" of bone matrix. In patients who are pregnant, obese, or with disorders (eg, celiac disease, cystic fibrosis, Crohn's disease, chronic kidney disease) or medications (eg, anticonvulsants, glucocorticoids, antifungals, and antiretroviral medications used in treatment of acquired immunodeficiency syndrome) affecting vitamin D absorption and/or metabolism, higher doses and more frequent monitoring might be required.

Bisphosphonates

⑨ Alendronate, risedronate, and intravenous zoledronic acid are approved by the FDA for postmenopausal, male, and glucocorticoid-induced osteoporosis. Intravenous and oral ibandronate and some specialized oral formulations of other bisphosphonates are indicated only for postmenopausal osteoporosis.

Pharmacology

Bisphosphonates mimic pyrophosphate, an endogenous bone resorption inhibitor.[2,64] Bisphosphonate antiresorptive activity results from binding to hydroxyapatite in bone with preference for areas with active bone remodeling. This leads to decreased osteoclast maturation, number, recruitment, bone adhesion, and life span.

Pharmacokinetics

Oral bisphosphonate bioavailability is less than 1% and is greatly decreased with concomitant food and beverages.[64,65] Within 24 hours of administration, bisphosphonates undergo rapid skeletal uptake and any medication not incorporated into bone is renally excreted. Elimination decreases linearly with declining renal function. Incorporation into bone gives bisphosphonates long biologic half-lives of up to 10 years. Bisphosphonates differ in the strength of binding to bone (zoledronic acid greater than alendronate which is greater than ibandronate which is greater than risedronate) with zoledronic acid having the greatest bone absorption and longest bone retention.

Efficacy

Bisphosphonates consistently provide fracture risk reduction and BMD increases (see Table 112-6) with noted difference in sites of fracture reduction between agents.[53] Fracture clinical trial data are from daily oral bisphosphonate or annual intravenous therapy, not weekly, monthly, or quarterly regimens.[65] Bisphosphonate comparative fracture prevention trials do not exist. Hip-fracture reduction has not been demonstrated with daily oral ibandronate; however, the study might have been underpowered.[2] Because of the lack of hip-fracture reduction data, ibandronate is not a first-line therapy (see Fig. 112-3). Annual intravenous zoledronic acid has documented secondary fracture prevention and a decrease in mortality when given after a first hip fracture.[53] Administration of intravenous zoledronic acid at an extended 18-month interval in women 65 years of age or older with osteopenia also decreased both vertebral and nonvertebral fractures over 6 years.

Bone turnover reaches an equilibrium with a lower rate of bone turnover evident within 3 to 6 months of bisphosphonate starting therapy, which results in BMD increases and a reduced fracture risk seen within the first 6 to 12 months.[53,65] For all bisphosphonates, increases in BMD are typically greater at the spine than at the hip.[53] Small increases in BMD continue for 4 to 5 years before plateauing. After discontinuation, the increased BMD is sustained for a prolonged period of time that varies based on different binding affinities of the individual bisphosphonates.[2] Because of the sustained effects, drug holidays can be considered for bisphosphonates.

The BMD increases with alendronate, risedronate, zoledronic acid, and oral ibandronate in men are similar to those in postmenopausal women.[6] Because of a lack of fracture data from pivotal trials in men, bisphosphonates are only FDA indicated to increase BMD, not to reduce fracture risk in men. However, no evidence suggests that efficacy profiles are expected to be different in men.

Adverse Effects

Oral bisphosphonates are well tolerated if patients are selected for therapy appropriately and the patient takes them correctly (see Table 112-8). Patients with creatinine clearances (CrCl) less than 30 to 35 mL/min (0.50-0.58 mL/s), who have serious GI conditions (abnormalities of the esophagus that delay emptying, such as stricture or achalasia), or who are pregnant should not take bisphosphonates. Some evidence suggest bisphosphonates can be used in select patients with age-related decline in renal function without added adverse effects.

GI complaints, including heartburn and dyspepsia, are one of the most common reasons cited by patients for discontinuing therapy.[2,65] While these mild GI effects are common, bisphosphonates are also associated with rare severe GI events, such as esophageal erosion, ulcer, or GI bleeding. If GI adverse events occur, switching to a different bisphosphonate or less frequent administration schedule might resolve the problem. Patients should be encouraged to discuss GI complaints with a healthcare provider. Intravenous zoledronic acid or ibandronate can be used for patients with GI contraindications or intolerances to oral bisphosphonates. Other common bisphosphonate adverse effects include injection reactions and musculoskeletal pain. If severe musculoskeletal pain occurs, the medication can be discontinued temporarily or permanently. Acute phase reactions (eg, fever, flu-like symptoms, myalgias, and arthralgias) are typically associated with intravenous administration, but rarely reported with oral bisphosphonates. This reaction usually diminishes with subsequent administration.

Rare adverse effects include osteonecrosis of the jaw (ONJ) and subtrochanteric femoral (atypical) fractures.[2] ONJ occurs more commonly in patients with cancer, receiving higher-dose intravenous bisphosphonate therapy. In osteoporosis, the incidence of ONJ is 0.001% to 0.01%. Maxillary or mandibular bone surgery and poor oral hygiene are dental-specific risk factors for development of ONJ. When possible, major dental work should be completed before bisphosphonate initiation. For patients already on therapy, some practitioners withhold bisphosphonate therapy during and after major dental procedures, but no data exist to support any benefit of such practice. Atypical femoral shaft fractures are rare but can occur without trauma. Some evidence suggests the risk could increase with longer duration of bisphosphonate use (greater than 5 years). Since some patients with atypical fracture experience prodromal thigh or hip pain, any such pain should be evaluated.

Interactions

Because of poor bioavailability, oral bisphosphonates should not be administered at the same time as other medications. The administration instructions described below should be followed.

Dosing and Administration

Because bioavailability is poor for bisphosphonates and to minimize GI side effects, each oral tablet should be taken with at least 6 ounces (~180 mL) of plain water (not coffee, juice, mineral water, or milk) at least 30 minutes (60 minutes for ibandronate) before consuming any food, supplements (including calcium and vitamin D), or medications (see Table 112-7). The patient should also remain upright (ie, either sitting or standing) for at least 30 minutes after alendronate and risedronate and 1 hour after ibandronate administration. For patients with swallowing difficulties (eg, stroke and tube feeding), an effervescent tablet form of alendronate, which is dissolved in 4 ounces (~120 mL) of room temperature water, could be used. This formulation has the same food restrictions as traditional oral tablets. In contrast, delayed-release risedronate is available, and it is administered immediately following breakfast with at least 4 ounces (~120 mL) of plain water. A patient who misses a weekly dose can take it the next day. If more than 1 day has lapsed, that dose is skipped. If a patient misses a monthly dose, it can be taken up to 7 days before the next administration.

Before intravenous bisphosphonates are used, the patient's serum calcium concentration must be normal. Serum creatinine should be monitored before each dose of zoledronic acid. The intravenous products need to be administered by a healthcare provider. The quarterly ibandronate injection is given intravenously over 15 to 30 seconds or can be diluted and given with a syringe pump. Zoledronic acid should be infused once yearly over at least 15 minutes with a pump. Acetaminophen can be given to decrease acute phase reactions.

Although these medications are effective, adherence is poor and results in decreased effectiveness.[2,66] Adherence is improved with once-weekly bisphosphonate administration over daily therapy; however, it is unclear if once-monthly therapy improves adherence more. While dosing frequency is a common barrier to adherence, adverse effects and concerns about adverse effects remain important predictors of adherence and persistence. Using decision aids in discussions about medication therapy choices and periodic follow-up with a healthcare professional could improve adherence and persistence to therapy. These decision aids visually display the pros of bisphosphonate therapy (ie, fracture avoidance) to the cons (ie, adverse effects) based on an individualized fracture risk.[67] To help overcome barriers associated with oral dosing frequency, intravenous ibandronate and zoledronic acid could be used as alternatives.

Duration

The ideal duration of bisphosphonate therapy is not known.[2] Bisphosphonates are deposited into the bone and continue to suppress bone turnover after discontinuation. Some adverse effects, such as atypical fracture, are associated with duration of therapy. To balance risk and benefit, some clinicians recommend a "bisphosphonate/drug holiday," defined as disruption of therapy during which medication effects exist with a plan for medication reinstitution. Two randomized, double-blind studies with a bisphosphonate/drug holiday after therapy with alendronate for 5 years or zoledronic acid for 3 years showed a continued fracture benefit after discontinuation of therapy. Because a beneficial response was predicted by hip T-score, experts recommend that a bisphosphonate holiday could be considered in postmenopausal women after 5 years of oral bisphosphonates or 3 years of intravenous bisphosphonates if no significant fracture history, hip BMD T-score is above –2.5, and fracture risk is not high. In women initially with very high fracture-risk who remain high-risk, continuing oral bisphosphonates for 10 years or intravenous bisphosphonates for 6 years should be considered. These recommendations are based on limited data and questions remain regarding what therapy to reinitiate and the applicability of this approach for men and patients with glucocorticoid-induced osteoporosis. Patients should be monitored during the drug holiday and restarting therapy considered if fractures occur or if there are significant BMD losses.

Denosumab

⑨ Denosumab is approved by FDA for the treatment of osteoporosis in postmenopausal women and men at high risk for fracture. It is also approved for glucocorticoid-induced osteoporosis and to increase bone mass in men receiving androgen deprivation therapy for nonmetastatic prostate cancer and in women receiving adjuvant aromatase inhibitor therapy for breast cancer who are at high risk for fracture.

Pharmacology

Denosumab is a fully human monoclonal antibody that binds to RANKL, blocking its ability to bind to its RANK receptor on the surface of osteoclast precursor cells and mature osteoclasts.[68] Denosumab inhibits osteoclastogenesis and increases osteoclast apoptosis.

Pharmacokinetics

Following subcutaneous injection, rapid suppression of bone turnover occurs within 12 hours.[68,69] Denosumab achieves peak concentration in approximately 10 days. The half-life is approximately 25 days, and the concentration slowly declines over a period of 4 to 5 months. The medication does not accumulate with repeated dosing at 6-month intervals. No dosage adjustment is necessary in renal impairment; however, hypocalcemia is more common in severe renal impairment. No studies have been conducted in hepatic impairment.

Efficacy

Over 3 years, denosumab significantly decreased vertebral fractures, nonvertebral fractures, and hip fractures in postmenopausal women with low bone density (see Table 112-6).[53] Continued increases in BMD are demonstrated with long-term treatment over 10 years. For postmenopausal women previously treated with oral bisphosphonates, switching to denosumab for 1 year provided greater increases in BMD at the spine and hip over switching to zoledronic acid; however, fracture outcomes are unknown.[2] Denosumab is not incorporated into bone and drug holidays are not recommended. Upon medication discontinuation, a rapid increase in bone turnover above baseline is noted with a corresponding loss of protection against vertebral fractures and case reports of multiple vertebral fracture. Therefore, for those with high fracture risk, denosumab therapy should be continued or alternative antiresorptive therapy (ie, bisphosphonate) should be initiated if denosumab is discontinued.

Adverse Events

In trials up to 10 years in duration, denosumab was generally well tolerated (see Table 112-8).[2] Dermatologic reactions not specific to the injection site and serious infections were noted in initial clinical trials, although an increased incidence has not been noted in long-term, follow-up trials nor with denosumab used in higher doses (Xgeva) for oncologic indications.[2]

As with bisphosphonates, rare, serious adverse effects from bone turnover suppression have been reported with denosumab including ONJ and atypical femoral fracture.[68] Major dental work should be completed before use when possible. Hypocalcemia can occur and any existing hypocalcemia should be corrected prior to use. Severe hypocalcemia is more common in patients with underlying kidney dysfunction. The manufacturer recommends monitoring of serum calcium, magnesium, and phosphorus within 14 days of administration in those with a CrCl less than 30 mL/min (0.50 mL/s).

Interactions

No interactions have been identified with denosumab.

Dosing and Administration

Denosumab is administered subcutaneously in the upper arm, upper thigh, or abdomen by a healthcare professional including pharmacists in some states. The product is available as a refrigerated prefilled syringe that can be stored at room temperature up to 14 days before administration (see Table 112-7).

Duration

After 5 to 10 years of therapy, patients should be reevaluated for medication continuation, discontinuation, or switching to a different medication.

Mixed Estrogen Agonists/Antagonists and Tissue Selective Estrogen Complexes

⑨ Raloxifene is a second-generation mixed estrogen agonist/antagonist (EAA; previously known as a selective estrogen receptor modulator, or SERM) approved by the FDA for prevention and treatment of postmenopausal osteoporosis and for reducing the risk of invasive breast cancer in postmenopausal women with and without osteoporosis. Raloxifene might be considered as a treatment option for women with no to minimal postmenopausal symptoms at low risk for hip fracture and with an increased breast cancer risk. Bazedoxifene is a third-generation EAA combined with conjugated equine estrogens (CEE) making it a TSEC that is approved by FDA for prevention of postmenopausal osteoporosis and vasomotor menopausal symptoms.[55,56] Bazedoxifene with CEE can be considered for younger postmenopausal women with a uterus, menopausal symptoms, and at risk for osteoporosis.[2,4,55,56]

Pharmacology

EAAs bind with α- and β-estrogen receptors and coactivators or corepressors to cause varying agonist or antagonist effects at different tissue sites.[55,56] Raloxifene is an agonist at bone receptors and antagonist at breast receptors and has minimal effect on the uterus. Bazedoxifene is an agonist at bone, and antagonist at the uterus and breast; however, reduction in breast cancer risk has not yet been demonstrated in large-scale clinical trials.

Pharmacokinetics

Food has a nonsignificant effect on absorption, which is about 2% for raloxifene and 6% for bazedoxifene due to extensive presystemic glucuronidation.[56,70,71] Raloxifene is 95% protein bound. The half-life of both raloxifene and bazedoxifene is 28 hours. EAAs are predominantly metabolized via glucuronidation and eliminated in the feces.

Efficacy

Raloxifene and bazedoxifene decrease vertebral but not hip fractures. In a post hoc analysis of the Multiple Outcomes with Raloxifene Evaluation trial, raloxifene decreased nonvertebral fractures in postmenopausal women with the most severe vertebral fractures at baseline. Bazedoxifene also decreased nonvertebral fractures in a subgroup of women with a higher fracture risk at baseline.[55,56] The fracture prevention effects of bazedoxifene combined with CEE are not known. EAAs increase spine and hip BMD, but to a lesser extent than bisphosphonates (see Table 112-6). Raloxifene's vertebral fracture prevention is greater in women without previous fracture.[4] Upon discontinuation, the medication effect of EAAs is lost, with bone loss returning to age- or disease-related bone loss rates. EAAs have a positive impact on the lipid profile but have not demonstrated a benefit on cardiovascular disease.[4,55]

Adverse Events

Hot flushes are common with raloxifene but decreased with bazedoxifene with CEE (see Table 112-8).[55,56,70,71] Raloxifene rarely causes endometrial thickening and bleeding; bazedoxifene decreases these adverse events making progestogen therapy unnecessary when it is combined with CEE. Leg cramps and muscle spasms are also common with both medications. Thromboembolic events are uncommon (less than 1.5%), but can be fatal. In large trials, no change in overall death, cardiovascular death, or overall stroke incidence was seen with raloxifene; however, a slight increase in fatal stroke (0.7/1,000 women – year difference) was documented, which resulted in a boxed warning for raloxifene.[55] Fatal stroke with raloxifene occurred most frequently in women with an increased risk of stroke at baseline. Bazedoxifene with CEE also has all the adverse effects listed for estrogens as a class including increased thromboembolic events.

Interactions

Because of raloxifene's highly protein bound nature (95%), when given concomitantly with other highly protein bound medications, like warfarin, a potential for binding interactions exists and, therefore, monitoring of both medications is suggested. Cholestyramine can decrease raloxifene absorption. Rifampin, phenytoin, carbamazepine, and phenobarbital can decrease bazedoxifene concentrations by inducing intestinal and liver uridine diphosphate glucuronosyltransferase (UGT) metabolism. Estrogen metabolism is altered with CYP3A4 and CYP1A2 inducers and inhibitors.

Dosing and Administration

EAAs/TSECs are administered orally once daily (see Table 112-7).[70,71] They are contraindicated for women with an active or past history of venous thromboembolic disease, pregnancy, or childbearing potential. Therapy should be stopped if a patient anticipates extended immobility. Women at high risk for a stroke or coronary events and those with known coronary artery disease, peripheral vascular disease, atrial fibrillation, or a prior history of cerebrovascular events might not be good candidates for EAAs/TSECs. These medications should be used with caution in patients with severe liver impairment or moderate-to-severe renal impairment due to a lack of data. Bazedoxifene with CEE has all the contraindications and precautions for estrogens as a class.

Calcitonin

⑨ Calcitonin is FDA indicated for osteoporosis treatment for women who are at least 5 years past menopause.[72] Intranasal calcitonin therapy (200 units daily) decreases vertebral fractures alone with no fracture reduction demonstrated with higher and lower doses (see Table 112-6).[2] Once calcitonin is discontinued, the benefits are lost over the next 1 to 2 years. A meta-analysis revealed a higher incidence of cancer in patients taking calcitonin. While the FDA found that evidence was insufficient for a causal relationship, calcitonin is considered a last-line therapy since there are more effective treatment options. Intranasal calcitonin might provide some short-term pain relief to some patients with acute vertebral fractures.

Dosing and Administration

Some patients do not like to administer medications intranasally (see Table 112-7). In clinical trials of calcitonin, a high dropout rate exists. If the nasal product is used for vertebral fracture pain, calcitonin should be prescribed for short-term (4 weeks) treatment and should not be used in place of other more effective and less-expensive analgesics nor should it preclude the use of more appropriate osteoporosis therapy.

Hormone Therapies

Estrogen

In women, estrogens with or without a progestogen significantly decrease fracture risk and bone loss (see Table 112-6).[2,4,34,36] Estrogen therapy is approved by FDA for prevention of postmenopausal osteoporosis but not for treatment. For women going through early menopause, estrogen therapy can be considered when protection against bone loss is needed in addition to reduction of vasomotor symptoms.[4,73] Other anti-osteoporosis therapies are reserved for treatment closer to the average age of natural menopause. Estrogens should not be prescribed solely for the prevention or treatment of osteoporosis if other anti-osteoporosis therapies can be used.[1,2,38] Oral and transdermal estrogens at equivalent doses and continuous or cyclic hormone therapy regimens have similar BMD effects. Effect on BMD is dose-dependent, with some benefit seen with lower estrogen doses. Fracture risk reduction has not been demonstrated with the lower doses. When estrogen therapy is discontinued, bone loss accelerates and fracture protection is lost. A complete discussion of adverse events, drug interactions, dosing, and administration for estrogen can be found in Chapter 102, “Hormone Therapy in Women.”

Testosterone

No fracture data are available, but some data demonstrate BMD improvements with testosterone use.[74] Testosterone is used to treat hypogonadism in men, but an osteoporosis medication should be added when risk for osteoporotic fracture is high.[12,74] A complete discussion of adverse events, drug interactions, dosing, and administration for testosterone products for men can be found in Chapter 103, “Erectile Dysfunction.”

Formation Medications

Parathyroid Hormone Analogs

⑨ Abaloparatide is an analog of PTHrP and teriparatide is an analog of PTH.[2,54] These agents are FDA indicated for the treatment of postmenopausal women with osteoporosis at high risk for fracture defined as multiple risk factors for fracture, a history of osteoporotic fracture, or failed or intolerant to other therapies. Teriparatide is additionally approved by FDA for osteoporosis in men who are at high risk for fracture or intolerant to other osteoporosis medications and glucocorticoid-induced osteoporosis. Patients who have a very high fracture risk, history of osteoporotic fracture, low bone density (eg, T-score less than –3.5), or have failed or are intolerant of previous bisphosphonate therapy could be candidates for PTH analog therapy.

Pharmacology

Teriparatide is a recombinant human product representing the first 34 amino acids in human PTH.[54] Unlike continuous PTH effects from primary hyperparathyroidism that can decrease BMD, when administered intermittently (ie, subcutaneously once daily) teriparatide increases bone formation with a minor increase in bone resorption for a net anabolic effect. Abaloparatide is a synthetic analog of PTHrP sharing the first 22 amino acids but with differing amino acids at positions 23 to 34. While both agents bind to the PTH type I receptor, abaloparatide binds with higher affinity to the RG confirmation, which results in an increased anabolic effect. Further, abaloparatide demonstrates less of an effect on activating bone resorption and remodeling than teriparatide. With both medications bone mass is improved.

Pharmacokinetics

Bioavailability for teriparatide and abaloparatide are 95% and 36%, respectively. The peptides are cleared through hepatic and extrahepatic pathways, with a half-life of 1 hour and 1.7 hours, respectively. Increases in the area under the curve are noted with decreasing renal function but there are no dosage adjustments noted in renal insufficiency. No studies have been performed in hepatic impairment. Alternative delivery formulations are being investigated.[54]

Efficacy

Two years of teriparatide or abaloparatide reduce vertebral and nonvertebral fracture risk in postmenopausal women (see Table 112-6).[53] Compared with alendronate, teriparatide has demonstrated reductions in vertebral fracture rates in patients taking glucocorticoids; however, no reductions in nonverterbral fractures were evident.[54] Lumbar spine BMD increases are greater than with antiresorptive agents. Observational data for teriparatide suggest a similar fracture benefit in men; no data are available regarding abaloparatide use in men. Discontinuation of parathyroid hormone analog therapy results in a decrease in BMD, which can be alleviated with subsequent antiresorptive therapy.[2]

Adverse Events

Transient hypercalcemia can occur and is less common with abaloparatide than with teriparatide (3.4% vs 6.4%, respectively) (see Table 112-8).[54] Because of an increased incidence of osteosarcoma in rats, both medications contain a box warning against use in patients at increased baseline risk for osteosarcoma (eg, Paget's bone disease, unexplained elevations of alkaline phosphatase, pediatric patients, young adults with open epiphyses, or patients with prior radiation therapy involving the skeleton). This adverse effect has not been seen in humans.

Interactions

An increased calcium concentration could be a concern in patients on digoxin therapy.

Dosing and Administration

Teriparatide and abaloparatide are commercially available as a prefilled pen delivery device (see Table 112-7). A daily subcutaneous injection is delivered to the abdominal area with site rotation. Teriparatide can also be given in the thigh. The administration of the first dose should take place with the patient either sitting or lying down in case orthostatic hypotension occurs. Both medications should be stored in the refrigerator before first use. After first use, abaloparatide can be kept at room temperature for up to 30 days. In contrast, teriparatide must be returned for storage in the refrigerator after each use and special precautions must be taken for travel. The teriparatide pen should be discarded after 28 days. Due to the theoretical risk for osteosarcoma, these medications are generally limited to 2 years of use cumulatively in a patient's lifetime with additional use of teriparatide considered on a risk-benefit basis. Suboptimal adherence is documented to decrease efficacy.

Besides the conditions listed above, parathyroid hormone analogs should not be used in patients with hypercalcemia, metabolic bone diseases other than osteoporosis, metastatic or skeletal cancers, previous radiation therapy, or premenopausal women of childbearing potential.

Formation and Antiresorptive Medication

Romosozumab

⑨ Romosozumab is approved by FDA for postmenopausal women at high risk for fracture defined as multiple risk factors for fracture, a history of osteoporotic fracture, or failed or intolerant to other therapies. This medication might be the anabolic osteoporosis medication of choice for patients with previous radiation therapy,[2] and those at risk for osteosarcoma and hypercalcemia.[75]

Pharmacology

Romosozumab is a humanized monoclonal antibody that binds to sclerostin to prevent inhibition of bone formation and decrease bone resorption, an activity that separates this medication from other anabolic medications.[54,75] By binding sclerostin, Wnt signaling can continue to increase gene transcription, which results in increased osteoblast synthesis, differentiation, and bone matrix building. This medication inhibits bone resorption by decreasing RANKL and m-CSF, and increasing OPG.

Pharmacokinetics

About 50% to 70% of a dose is absorbed. Peak serum concentrations after subcutaneous administration are reached within 3 to 4.5 days, with no accumulation with subsequent doses. Romosozumab has a half-life of 6 to 7 days.

Efficacy

After 1 year of romosozumab, vertebral fractures are statistically decreased by 73%, with a nonsignificant decrease in nonvertebral fractures by 25% in postmenopausal women (see Table 112-6).[2,39,54,75] Fracture prevention was higher if the study participants in Latin America were removed from the multi-country study analysis because this cohort had lower fracture rates even in the placebo arm. Fracture risk was also decreased by 48% for vertebral fractures, 19% for nonvertebral fractures, and 38% for hip fractures after 1 year of romosozumab followed by 1 year of alendronate. Lumbar spine and hip BMD statistically increased after 1 year of romosozumab treatment. To prevent BMD loss after discontinuation, therapy with denosumab or alendronate for 1 year after romosozumab resulted in BMD continuing to increase at hip and bone sites. Vertebral, femoral neck, and hip BMD and hip bone strength increased after romosozumab therapy in postmenopausal women who had received at least 3 years of prior bisphosphonate therapy.[73] These BMD increases were not as large as reported in bisphosphonate naïve women but were greater than teriparatide therapy BMD effects after bisphosphonate therapy. Comparing published results in postmenopausal women, romosozumab might be better to prevent hip fractures compared to abaloparatide and teriparatide while these last agents might be better for vertebral fracture prevention.[75] Romosozumab increased BMD in men by 12.1% at the lumbar spine, 2.5% total hip, and 2.2% femoral neck, all significantly different than placebo after 1 year of therapy.[54] Fracture data were not captured in men.

Adverse Effects

Headache and arthralgia were the most common adverse effects, followed by hypercalcemia (<1%) (see Table 112-8).[2,39,54] Mild injection site irritation occurred in 6% to 8% of patients. Romosozumab antibodies developed in 10% to 20% patients, sometimes being transient. The antibodies generally are not neutralizing antibodies nor did they alter efficacy. Serious cardiovascular events have been reported in a few trials, but the incidence is low (<2.5%) and not much higher nor significantly different from the alendronate treatment arm (1.9%) in postmenopausal women at 1 year. The serious cardiovascular events increased to 6.5% and 6.1%, respectively, after both arms were switched to alendronate for year 2. In men, the cardiovascular event rates were 4.9% in men receiving romosozumab versus 2.5% receiving placebo. Myocardial infarction, stroke, and cardiovascular death are listed as a boxed warning. Romosozumab should not be used within 1 year of a myocardial infarction or stroke and benefit risk evaluation should be conducted in patients at risk for these conditions or with these conditions in their past medical history. Rare cases of ONJ and atypical femoral fractures have been reported. Because Wnt signaling is also related to malignancies, the medication-induced increased activity could be a concern. However, this adverse effect was not seen in the premarketing clinical trials.

Interactions

None

Dosing and Administration

The medication comes as two prefilled syringes requiring refrigeration until administered by a healthcare provider. Each syringe is injected into two different sites during the same visit (see Table 112-7). Patient self-administration is being explored.

Sequential and Combination Therapy

⑨ In sequential therapy, an anabolic agent is given first to increase bone remodeling units and bone mass, followed by an antiresorptive agent to continue with bone formation. Although this sequential therapy is recommended in the guidelines, in practice this regimen is generally reserved for patients with severe osteoporosis because of the cost of anabolic agents. Starting with an antiresorptive first and then switching to teriparatide results in lower BMD compared to starting with the bone formation medication first. Thus starting teriparatide after antiresorption therapy is not recommended.[2] However, this therapy will be used, especially for patients who have fractured or continue to lose bone mass while on antiresorptive therapy. Romosozumab can be used after previous treatment with parathyroid hormone analogs.[2] Small increases in BMD can be seen when switching from an oral bisphosphonate to denosumab. Switching to denosumab thus can be used during a bisphosphonate drug holiday or for bisphosphonate treatment failures (ie, BMD decreases or fracture).

Because of no documented fracture benefit, increased cost, concern for dual suppression of bone turnover, and potential for more adverse effects, combination therapy is rarely used.[2,53,54] Combination therapy of two antiresorptive agents or two anabolic agents did not increase bone mass compared to monotherapy even though they have different pharmacologic properties. Combination of teriparatide with oral bisphosphonates generally resulted in less BMD gains than monotherapy, and thus is not used. Combination teriparatide and denosumab resulted in greater hip BMD effects, but long-term results were generally similar to sequential therapy. Estrogen therapy combined with a bisphosphonate did not increase bone mass more than monotherapy. Antiresorptive therapy can be initiated after estrogen discontinuation to help negate the accelerated bone loss that occurs once estrogen is stopped. For postmenopausal women with menopause symptoms and an osteoporosis diagnosis, an osteoporosis medication should be prescribed along with menopausal hormone therapy. When raloxifene is used for breast cancer prevention, sometimes another antiresorptive agent will be prescribed, especially if hip fracture risk is high.

SPECIAL POPULATIONS

Osteoporosis is a particular threat in some subgroups because of age, genetic abnormalities, diseases, and medications.

Children and Adolescents

⑥ Osteoporosis in children and adolescents is uncommon but can lead to significant pain, deformity, and chronic disability. Pediatric osteoporosis is due to genetic disorders such as osteogenesis imperfecta and idiopathic juvenile osteoporosis, or secondary causes including chronic inflammatory diseases, growth hormone deficiency, celiac disease, diabetes, anorexia nervosa, and glucocorticoid use (see Tables 112-2 and 112-3 for other causes). Female athlete triad and anorexia nervosa, which are common in this age group, can lead to osteoporosis and fractures.

The diagnosis and treatment of osteoporosis in children and adolescents are challenging. Low bone mass is defined as a Z-score of −2.0 or less (adjusted for gender, age, and race/ethnicity) or T-score < -2.5 when adult height has been achieved using central DXA of the spine or total body minus head.[10,15] Ability to lie still during the DXA and radiation doses of some tests create concerns for this age group. Routine DXA monitoring is not required[10]; however, some criteria for this test have been suggested.[15] An osteoporosis diagnosis requires a DXA Z-score of −2.0 or less and 2 long-bone fractures by age of 10 or 3 long-bone fractures by the age of 19.[10] DXA monitoring is done every 1 to 2 years for bone health and annually for children on bisphosphonate therapy.[10] Spine x-rays can also be monitored every 6 months to 2 years. Genetic testing might be required to identify an underlying cause.[15]

The first step in management is correcting any underlying primary or secondary causes and instituting a bone-healthy lifestyle especially adequate calcium, vitamin D, and exercise.[10,15,58] This step includes weight gain for anorexia nervosa and decreased exercise intensity for those with the female athlete triad.

Pharmacologic treatment has been used for children and adolescents with low bone mass and fragility fractures. Unlike adults, many children can reshape vertebral fractures and reclaim more BMD with treatment.[58] Growth hormone can be helpful in children with a documented deficiency but has no effect if no underlying deficit.[57] The optimal osteoporosis medication, dose, and duration of therapy are unknown and can vary by age and cause of osteoporosis. More safety data are needed.[15,58]

Bisphosphonates can be used off-label in children/adolescents but should be discontinued when the Z-score goes above -20.[10] Children and adolescents on glucocorticoids frequently need bisphosphonate therapy for longer periods.[10,15,58] For children less than 40 kg, the alendronate dose is 5 mg/day or 35 mg/week and risedronate is 15 mg/week.[10] Zoledronic acid is dosed 0.0125 to 0.05 mg/kg (maximum dose 4 mg) every 6 to 12 months. A major concern with bisphosphonates is their effect on longitudinal bone growth and modeling. Fracture healing, skeletal growth/maturation, and the appearance of growth plates do not appear to be impaired by bisphosphonates. Because bisphosphonates are released from bone for many years and cross the placenta, teratogenic effects are also a concern. Bisphosphonates should not be used if pregnancy is planned within the year. Pediatric experience with denosumab is limited but positive.[57]

Teriparatide has a box warning to avoid use in children due to a concern for osteosarcoma. Newer agents have not been evaluated in pediatric patients.

Premenopausal Women

⑥ Clinically significant bone loss and fractures in healthy premenopausal women are rare.[73] Risk factors are similar between premenopausal and postmenopausal osteoporosis. While bone loss occurs during pregnancy and lactation, it is usually gained back 6 to 12 months after pregnancy or breastfeeding is complete. Secondary causes are involved in 50% to 90% of premenopausal women with osteoporosis (see Tables 112-2 and 112-3) for the bone loss.[11] Common secondary causes in this group are amenorrhea, anorexia nervosa, glucocorticoid use, and celiac disease. Premenopausal women with prior fracture have a higher risk of postmenopausal osteoporotic fractures.[11,73,76]

Routine bone density screening should not be performed in healthy premenopausal women. Premenopausal women with known osteoporosis risk factors and low-trauma fractures can undergo central DXA examinations.[73] In this case, the Z-score is used, with Z-scores of −2.0 or less defined as bone mass below the expected range for age.[11,37,73,76] The categorization of osteopenia or osteoporosis based on T-score alone should be avoided in premenopausal women unless there is a history of low-trauma fracture or a secondary cause of osteoporosis.

Pharmacologic therapy for osteoporosis should be used with caution in premenopausal women as antifracture efficacy and safety have not been adequately demonstrated.[11,73] All premenopausal women should practice a bone-healthy lifestyle, including adequate calcium and vitamin D intake. Secondary causes of bone loss should be resolved. For example, gaining weight and resumed menses are more effective in correcting bone loss secondary to anorexia nervosa than oral contraceptives.[73,76] If the contributing factor cannot be eliminated, for example, chemotherapy or glucocorticoids, pharmacological therapy can be considered. Women with an unidentified cause for osteoporosis and no history of fracture should be treated with a bone-healthy lifestyle and watchful waiting.

Osteoporosis medication safety during pregnancy and breastfeeding have not been adequately studied. While some data suggest that use prior to conception and during the first trimester of pregnancy is safe, bisphosphonates are generally not used in women of childbearing age due to concern for fetal harm resulting from the long half-lives of these agents.[73,76] Bisphosphonate use should be avoided within 12 months of conception and use of contraceptive agents should be encouraged to reduce the likelihood of becoming pregnant during therapy. Human data on the safety of denosumab and bone-forming agents such as teriparatide in pregnancy are lacking, however, some animal data suggest congenital defects following exposure. Therefore, these agents should be avoided during pregnancy[11]

Older Adults

Although osteoporosis, osteoporotic fractures, and postfracture morbidity and mortality increase with age, osteoporosis is underdiagnosed and undertreated in older adults. One-third of older adults older than 65 years old and about 50% of older adults older than 80 years old fall annually; with 20% to 30% of these falls resulting in moderate to severe injury.[2] More than 50% of women older than 75 years old have osteoporosis. Fewer than 25% of older adults had a DXA completed or received osteoporosis medications after a fracture. After a hip fracture, more than 50% of older adult women will require assistance including long-term nursing home residence (25%).[2,4] Only 33% of nursing home residents with an osteoporosis diagnosis or past fracture received an osteoporosis medication, even though 89% of them were considered at high risk for a fracture.[77] Hypogonadism is present in about 29% of older men.[12] Sarcopenia resulting in decreased muscle mass and function is prevalent in older adults[8]and is associated with increased falls and fractures.[78]

Guidelines recommend central DXA for adults aged 65 years and older; however, all older adults are not evaluated for osteoporosis. Reference standards for osteoporosis assessment tools are generally not available for the oldest older adults (eg, maximum age for FRAX is 90 years). In clinical practice, estimates for a 90-year-old person are applied to those adults older than 90 years. FRAX slightly overestimates whereas ultrasound underestimates osteoporosis in nursing home residents. In an older adult with falls, the Garvan calculator might be preferred since it includes falls whereas FRAX does not.[2]

Older adults should practice a bone-healthy lifestyle, ingest adequate calcium and vitamin D, and implement measures to prevent falls (see above sections).[2,8,12,14,79] While some guidelines recommend adequate amounts of calcium and vitamin D, the USPSTF feels evidence is insufficient to support fall and fracture prevention with supplementation. Lactose intolerance and hypercholesterolemia increase with aging and can lead to lower calcium intake from dairy products, which can increase the need for calcium supplements. Limited sun exposure due to frailty and institutional residence can increase the need for vitamin D supplementation for bone and muscle health. Protein intakes of 1 g/kg/day (up to 1.5 g/kg/day for some chronic illnesses) are suggested, and these also help with decreasing sarcopenia. Exercise might be difficult in older adults due to osteoarthritis or limited by underlying cardiac and respiratory diseases. However, walking and lifting light weights can still stimulate bone remodeling. Encouraging older adults to do a home safety evaluation for falls can assist with fracture prevention. Multidisciplinary fall prevention programs with multiple interventions generally have greater impact on fall prevention than single discipline or single intervention.[47] Exercise is a major component of these interventions. Many fall prevention materials are available without cost on the Internet.

Some data exist to support osteoporosis medication benefits in older adults; however, data are limited for the oldest older adults.[8,14,75] In a Medicare study, antiosteoporotic medications after a fracture lowered subsequent fracture risk by 21%. When deciding whether to use prescription medications in older adults, the following factors need to be taken into consideration: remaining life span, ability to take and afford medications, cognitive function, swallowing ability, GI disorders, polypharmacy, desire to avoid additional medications, and regimen complexity. Challenges with oral bisphosphonate administration requirements exist for older adults who are bed bound, have difficulties swallowing, have fluid restrictions for cardiovascular or kidney diseases, forget to drink adequate amounts of fluid, or cannot stay upright for the given time. Diuretics, nephrotoxic medications, and dehydration can increase acute and chronic renal failure when zoledronic acid is administered too quickly.[2]

The cost of antiosteoporosis medications can quickly cause an older adult with the Medicare Part D (medications) to enter the coverage gap, or "donut hole," which is the period when out-of-pocket medication expenses can be higher. Having to pay for antiosteoporosis medications might create adherence problems. Sometimes not initiating or stopping osteoporosis medications might be warranted for older adults with conditions such as severe Alzheimer disease or during palliative or hospice care. Comprehensive medication reviews and deprescribing can decrease all-cause mortality and potentially inappropriate medication use but does not increase nor decrease falls.[50]

Chronic Kidney Disease

Low BMD and fractures occur in patients with chronic kidney disease (CKD, glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2 [0.58 mL/s/m^2]), using chronic dialysis, and/or after kidney transplant.[80] Some medications for CKD and transplant can further compromise bone health. Fractures occur earlier and have greater 1-year mortality rates (64%). Osteoporosis and decreased renal function due to aging are different from other chronic kidney disease-mineral and bone disorders (CKD-MBD) such as renal osteodystrophy (see Chapters 69 "Calcium and Phosphorus Homeostasis" and 62 "Chronic Kidney Disease"), which can be related to high bone turnover, adynamic bone, or a combination of both. A DXA with VFA when appropriate can be used to assess bone loss and FRAX can be used to determine fracture risk; however, neither assessment distinguishes between renal and nonrenal causes of bone loss.[81] The DXA result can underestimate fracture risk since changes in bone quality from CKD are not captured. Similarly, FRAX can underestimate risk since renal failure is not included as a risk factor. When the diagnosis of the underlying bone disease pathophysiology could influence treatment, a bone biopsy can be conducted but is no longer a Kidney Disease Improving Global Outcomes (KDIGO) requirement.[80] Laboratory tests such as serum calcium, 25 (OH) vitamin D, intact PTH, and serum phosphorus can help with identifying underlying CKD-MBD. Non-kidney-retained BTM such as bone-specific alkaline phosphatase (BSAP), PINP and tartrate-resistant acid phosphatase 5b (TRAP 5b) can be used to monitor therapy and guide reinstitution of therapy after a bisphosphonate drug holiday.[81] Other markers are being investigated.[80]

The first treatment step is to manage underlying disease conditions, including calcium and vitamin D abnormalities, hyperphosphatemia, and hyperparathyroidism (discussed in Renal Disorders chapters of this textbook).[80] Limited data exist on anti-osteoporosis medications for patients with CKD, dialysis, and/or post kidney transplant.[2,80,81] Calcium intake is preferred by diet with supplements used only to achieve RDAs when diet is insufficient. A 25 (OH) vitamin D level is obtained to assess bone health with vitamin D treatment prescribed as needed to maintain therapeutic concentrations, which are the same as non-CKD patient recommendations. Sometimes 1,25-$(OH)_2$-vitamin D might also be used for underlying CKD induced deficiencies, creating a need for adding prescription calcitriol therapy to over-the-counter vitamin D therapy.

Osteoporosis medication studies in patients with CKD are lacking and often with insufficient sample sizes or were post hoc analyses.[2,80,81] Denosumab is not renally eliminated and thus can be used. When denosumab is used in CKD-MBD or dialysis, serum calcium levels need to be monitored since these patients can develop hypocalcemia, especially if also receiving calcium-sensing receptor agonists. According to product labeling, oral bisphosphonates are not recommended and zoledronic acid is contraindicated if CrCl is less than 30 or 35 mL/min (0.50 or 0.58 mL/s). However, guidelines suggest bisphosphonates can be used, particularly when decreased renal function is the result of aging alone. Insufficient data exist to support lower doses for shorter durations, which have been suggested to account for decreased renal bisphosphonate elimination. Dialysis does eliminate bisphosphonates, but if the dose is given after dialysis, a lower dose or longer interval is suggested.[80] Bisphosphonates should not be given at the same time as phosphate binders or other medications. Patients with CKD should be reassessed in 3 years or after a fracture for bisphosphonate continuation decisions. Raloxifene is not suggested for patients with severe renal impairment. Teriparatide can help patients with adynamic bone and those with low PTH and BMD but not patients with high bone turnover. A role for abaloparatide and romosozumab could exist since these medications are not renally eliminated, do not accumulate in bone, and can overcome some CKD-MBDs; however, little evidence is available to guide use. Since many patients with decreased renal function have cardiovascular disease, use of romosozumab might be limited. Fracture risk increases with anti-osteoporosis medication discontinuation, so a postdiscontination plan is needed. Kidney and/or bone specialists usually provide care to patients with significant kidney disease and osteoporosis.

Drug-Induced Osteoporosis

Glucocorticoid-Induced Osteoporosis

③ Glucocorticoid use is the most common cause of medication-induced osteoporosis. Up to 40% of patients taking chronic oral glucocorticoids will experience a clinical fracture or show evidence of vertebral fracture on x-ray.[82,83] In patients who take 2.5 to 7.5 mg/day of prednisone or the equivalent, the relative risk of vertebral fracture doubles and the relative risk of hip fracture increases by 50%.[84] All glucocorticoid doses and formulations have been associated with increased bone loss and fractures; however, risk is much greater with prednisone doses of 5 mg or more daily or equivalent and with oral therapy versus inhaler and intranasal therapy.[84,85] Although a well-documented risk, many patients receiving glucocorticoids are not evaluated or treated for glucocorticoid-induced osteoporosis (GIO); therefore, greater vigilance by all healthcare professionals is needed.[82,84]

Bone losses with glucocorticoids are rapid with up to 12% loss over the first year. The greatest decrease occurs in the first 3 to 6 months of therapy. Afterward, bone loss is about 2% to 3% per year.[84] The risk of fracture increases within 3 months of initiating glucocorticoid therapy and peaks at 1 year. Trabecular bone is affected more than cortical bone; therefore, vertebral fractures are more common. The pathophysiology of glucocorticoid-induced bone loss is multifactorial.[83] Glucocorticoids decrease bone formation through decreased proliferation and differentiation and enhanced apoptosis of osteoblasts. They can interfere with the bone's natural repair mechanism through increased apoptosis of osteocytes. Glucocorticoids increase RANKL and decrease OPG, leading to an increase in the number of osteoclasts and increased bone resorption. They can reduce estrogen and testosterone concentrations. A negative calcium balance is created from decreased calcium absorption and increased urinary calcium excretion via alterations in calcium transporters. The underlying disease requiring glucocorticoids (see Table 112-2) also can negatively affect bone metabolism.

FRAX and central DXA are recommended by current guidelines for evaluation, though neither adequately accounts for the rapid increase in fracture risk following glucocorticoid initiation.[82,83] Since FRAX does not account for specific dose, duration or accumulation of glucocorticoids, scores must be adjusted based on prednisone dose or equivalent.[82] For those taking more than 7.5 mg or equivalent per day, FRAX risk of major osteoporotic fracture should be increased by 15% (ie, multiplied by 1.15) and FRAX risk of hip fracture by 20% (ie, multiplied by 1.2). Based on glucocorticoid-adjusted FRAX estimates of the 10-year risk of major osteoporotic fracture and hip fracture, the patients are risk stratified into low, moderate, and high risk for fracture. Criteria for classification into a risk category is detailed in Table 112-9. An initial BMD assessment is recommended prior to or within 6 months of glucocorticoid initiation for adults 40 years of age or older and for adults under the age of 40 with a history of fragility fracture or other risk factors. Repeat BMD testing is recommended every 2 to 3 years during osteoporosis therapy for those taking high-glucocorticoid doses (30 mg of prednisone or more per day or a cumulative dose greater than 5 g in the past year), a fracture 18 months or more after starting osteoporosis therapy, medication adherence or absorption concerns, or other risk factors for osteoporosis. VFA is also suggested for patients receiving 5 mg or more prednisone or equivalent daily for 3 months or more.[37]

TABLE 112-9

Classification of Fracture Risk in Patients Treated with Glucocorticoids

Fracture Risk	Adults ≥40 years old	Adults <40 years old
Low	FRAX[a] 10-year risk of major osteoporotic fracture <10% FRAX[a] 10-year risk of hip fracture ≤1%	None of the risk factors listed below for moderate- or high-fracture risk
Moderate	FRAX[a] 10-year risk of major osteoporotic fracture 10%-19% FRAX[a] 10-year risk of hip fracture >1% and <3%	Hip or spine BMD Z-score <−3.0, or rapid bone loss (≥10% at the hip or spine over 1 year) and continuing glucocorticoid therapy with ≥7.5 mg/day for ≥6 months
High	History of osteoporotic fracture, or hip or spine BMD T-score ≤−2.5 in men ≥50 years old and postmenopausal women, or FRAX[a] 10-year risk of major osteoporotic fracture ≥20%, or FRAX[a] 10-year risk of hip fracture ≥3%	Prior osteoporotic fracture

[a] If glucocorticoid treatment is >7.5-mg prednisone or equivalent per day, the FRAX risk score should be multiplied by 1.15 for major osteoporotic fracture and by 1.2 for hip fracture and then used to determine overall fracture risk.

Date from Reference 82.

All patients using glucocorticoids should practice a bone-healthy lifestyle and minimize glucocorticoid exposure when possible.[82–84] All patients starting or receiving glucocorticoid therapy (any dose or duration) should consume 1,000 to 1,200 mg elemental calcium and 600 to 800 units of vitamin D daily or more to achieve therapeutic 25 (OH) vitamin D concentrations. Minimizing fall risk is important. Osteoporosis prevention counseling should occur for all patients using this medication for three months or more regardless of dose. Glucocorticoids should be used at the lowest dose and for the shortest duration possible. Upon discontinuation of glucocorticoid therapy, fracture risk decreases and BMD increases, though they might not increase to baseline levels.[84]

Alendronate, risedronate, zoledronic acid, denosumab, and teriparatide are approved by FDA for GIO.[84] The current guidelines from the American College of Rheumatology divide recommendations for prescription osteoporosis medication use in GIO by fracture risk and age (see Tables 112-9 and 112-10).[82] Therapy recommendations are based on comparative efficacy, potential for toxicity, and cost.

TABLE 112-10

Therapy to Prevent or Treat Glucocorticoid-Induced Osteoporosis in Adults Beginning Long-Term Glucocorticoid Treatment (≥2.5-mg Prednisone or Equivalent Per Day for ≥3 months)

Patient Population	Low-Fracture Risk	Moderate-Fracture Risk	High-Fracture Risk
All	Optimize calcium and vitamin D intake; bone-healthy lifestyle	Optimize calcium and vitamin D intake; bone-healthy lifestyle	Optimize calcium and vitamin D intake; bone healthy lifestyle
Adults age ≥40 years	No prescription osteoporosis therapy	Oral bisphosphonate alternatives: IV bisphosphonate, teriparatide, denosumab, or raloxifene[b]	Oral bisphosphonate alternatives: IV bisphosphonate, teriparatide, denosumab, or raloxifene[b]
Adults age <40 years	No prescription osteoporosis therapy	Oral bisphosphonate alternatives: IV bisphosphonate, teriparatide, or denosumab	Oral bisphosphonate alternatives: IV bisphosphonate, teriparatide, or denosumab
Women of childbearing potential[c,d]	No prescription osteoporosis therapy	Oral bisphosphonate Alternative: teriparatide	Oral bisphosphonate Alternatives: teriparatide, IV bisphosphonate, or denosumab

IV, intravenous.

[a] Listed in order of preference; abaloparatide and romosozumab were not yet approved during guideline development.

[b] Recommended only for postmenopausal women when other alternative therapies cannot be used.

[c] Women of childbearing potential who do not intend to become pregnant during the osteoporosis treatment period and are using effective birth control or are not sexually active.

[d] Fetal risks from osteoporosis medications during pregnancy.

Data from Reference 82.

Oral bisphosphonates are recommended first-line, though intravenous bisphosphonates can be used in patients who are not adherent or unable to take the oral preparations. Teriparatide is recommended for patients who cannot use a bisphosphonate, and denosumab is recommended if neither a bisphosphonate nor teriparatide can be used. Denosumab is not recommended first-line for GIO due to limited safety data in this population. Consideration should be given to potential risk of infection in patients taking immunosuppressive agents or biologic therapies. Raloxifene does not have a FDA indication for GIO, but does have some clinical data documenting improved BMD at the lumbar spine in patients taking glucocorticoids.[84] It is recommended only in postmenopausal women if no other osteoporosis medications can be used. Standard osteoporosis therapy doses are used. The recommendations are similar for women of childbearing potential who do not plan to become pregnant and are using an effective contraceptive or are not sexually active.[82]

Patients receiving glucocorticoids are considered high risk, and, therefore, a bisphosphonate drug holiday is generally not considered after 5 years. Bisphosphonate treatment for 7 to 10 years is recommended if patients continue glucocorticoid use. Since glucocorticoids can cause hypogonadism, sometimes hormone therapy will be prescribed. The hormonal therapy for correcting hypogonadism symptoms most likely will have some positive bone effects as well.

Cancer Treatment–Induced Bone Loss

3 Cancers, some associated treatments and metastatic bone disease can cause bone loss and osteoporosis.[59,63] Medications used to treat hormone-responsive cancers — such as aromatase inhibitors and androgen deprivation therapy, and some cytotoxic chemotherapies — are associated with a reduction in BMD. Chemotherapy-induced ovarian failure can enhance bone loss. Glucocorticoids used as chemotherapy, chemotherapy premedication, and/or treatment for chemotherapy-induced nausea and vomiting also increase bone loss in patients with cancer.

Central DXA screening is advocated for patients at high risk for osteoporosis, which would include certain chemotherapies and cancers.[59] *Patients with at least 1 risk factor should be offered BMD testing with central DXA. In patients on medications that cause bone loss or whose BMD is near the threshold of treatment with FRAX, BMD testing should be offered every 2 years or more frequently considering the results of the BMD and anticipated bone loss, but not more than annually. FRAX can be used to estimate the risk for osteoporotic fracture; however, it has not been validated in patients with cancer.* When using FRAX, secondary osteoporosis can be checked “yes” when premature menopause and/or hypogonadism caused by chemotherapy and cancer are present, though fracture risk is likely still underestimated in this group.[86]

Certain osteoporosis medications are used to prevent bone loss or treat osteoporosis due to chemotherapy, cancer, and metastases. Bisphosphonates and denosumab decrease chemotherapy-induced bone loss and in some trials, reduce fractures.[59] Most research has been conducted in women with breast cancer and men with prostate cancer. Raloxifene decreases the risk of invasive breast cancer in high-risk women.[2,34] Due to risk of osteosarcoma, teriparatide and abaloparatide are specifically contraindicated in patients with bone metastases or prior radiation to the skeleton. Zoledronic acid and denosumab are used for cancer-related hypercalcemia and skeletal-related events.[63] They are marketed with different product names for these indications since dosages are much higher than for osteoporosis. For additional information see Chapter 150, “Supportive Care in Cancer.”

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of Patient-Centered Care Plan

10 Assessment of adherence and tolerability of medication should be performed during each encounter patients have with the healthcare system. Having patients repeat back instructions for medication administration will help identify administration problems and enable timely correction. Assessment of fracture, back pain, and height loss can help identify worsening osteoporosis.

The role of routine monitoring of BMD via central DXA is controversial and recommendations vary since change in BMD is only one component of fracture risk.[2,87] Nonetheless, decreases in BMD while on treatment are associated with increases in fracture risk compared to stable or increased BMD. Since BMD continues to decrease with aging, no change from baseline can be an acceptable response. However, BMD is considered a failure if BMD significantly decreases while on treatment. This treatment failure could indicate nonadherence, a lack of response, or the presence of secondary causes contributing to continued bone loss.[2] To minimize test variability, BMD testing should be performed on the same DXA machine. A statistical change needs to be greater than the least significant change for that specific piece of equipment based on local data with the team of technicians.

The AACE/ACE guidelines recommend central DXAs every 1 to 2 years after medication initiation until BMD is stable at which time the interval for reassessment could be lengthened.[2] The Endocrine Society guidelines recommend waiting 3 years for zoledronic acid, 5 years for other bisphosphonates, and 5 to 10 years for denosumab.[39] Financial support for testing at intervals less than 2 years might not be provided by insurance plans. In patients with conditions associated with higher rates of bone loss (eg, glucocorticoid use and certain chemotherapy agents), more frequent monitoring might be warranted.

Like central DXA, BTM can be used to identify nonadherence and lack of response to therapy.[2] The markers are measured 3 to 6 months after therapy initiation and compared to baseline values.[2,88] Significant changes need to be greater than the least significant change for that test.[2] Because no consensus on result interpretation and high-test variability exists, these tests are not routinely ordered.

Osteoporosis Services

⑩ Despite the availability of effective therapies, many patients (approximately 70%) are not being evaluated or do not receive appropriate osteoporosis therapy.[2] In fact, the proportion of patients receiving osteoporosis medication following a hip fracture has decreased. People of color receive even fewer DXA screenings and less medication therapy, and have poorer results after a fracture.[3] To combat this trend, many institutions are implementing an Own the Bone program or a fracture liaison service, which is generally an interprofessional, multifaceted program to increase treated patient numbers, enhance adherence, and improve osteoporosis treatment outcomes. All providers and programs should work to decrease health disparities in osteoporosis prevention and treatment.[3] Communicating risk is important for people to understand their risk for and consequences of fractures, especially in relation to other medical conditions.[2] Community pharmacists and other healthcare professionals can provide osteoporosis screenings using the FRAX tool to estimate fracture risk in the community, especially at health fairs. Osteoporosis prevention and treatment services have been clinically successful in community pharmacies and in ambulatory care settings. At 1 year, only 26% to 56% of patients still use their osteoporosis medications. Thus, all healthcare professionals should identify and resolve barriers to optimal medication initiation and adherence. The main reasons for nonadherence are medication cost, fear of adverse effects, resistance to medication use, and perceived lack of medication need. Routine follow-up with healthcare professionals and enhanced risk-benefit communication tools could improve treatment and adherence rates. Databases can be used to identify patients after a low-trauma fracture who have not had a DXA screening or osteoporosis medication started. Patient medication assistance programs can be used to decrease cost.

To improve patient care, the US Centers for Medicare and Medicaid Services have created this quality measure—the percentage of women 50 to 85 years old with a recent fracture that is screened or treated within 6 months.[1,44,89] Financial incentives tied to these measures could help bridge the gap in quality of care.

CONCLUSION

Osteoporosis prevention begins at birth and continues throughout life by practicing a bone-healthy lifestyle (adequate calcium and vitamin D intake, exercise, no smoking, minimal alcohol use, and fall prevention). Generally, osteoporosis occurs in postmenopausal women and older men; however, the disease can occur in all ages because of secondary causes such as genetics, diseases, and medications. FRAX tool can be used for screening and to assist in identifying patients at high risk for fracture requiring treatment. Central DXA can be used for osteoporosis screening, diagnosis, and monitoring.

Alendronate, risedronate, zoledronic acid, and denosumab are first-line therapies for those with high fracture risk since these medications decrease hip, nonvertebral, and vertebral fractures. Abaloparatide, romosozumab, and teriparatide are the only medications that can build bone; however, cost, subcutaneous administration, and lack of hip fracture prevention limit their use. Although medications decrease fracture risk, prescribing of osteoporosis medications and patient adherence to them is suboptimal. All healthcare professionals need to be actively involved with people of all ages to provide osteoporosis education and counseling, prevent osteoporosis development across the lifespan, treat osteoporosis, and improve medication adherence to prevent osteoporotic fractures.

ABBREVIATIONS

25(OH) vitamin D	25-hydroxyvitamin D/calcidiol
APC	adenomatous polyposis coli
ATPase	adenosine triphosphatase
BMD	bone mineral density
BMP	bone morphometric proteins

BSAP	bone-specific alkaline phosphatase
BTM	bone turnover markers
Calcium	Ca^{++}
Cbfa1	core-binding factor alpha 1
Cbl	E3 ubiquitin ligase
CEE	conjugated equine estrogens
Csk1α	casein kinase 1α
CKD-MBD	chronic kidney disease-mineral and bone disorder
CrCl	creatinine clearance
CTX	c-terminal type 1 collagen telopeptide
Dkk-1	Dickkoff-1
DPD	deoxypyridinoline
DSH	disheveled cytoplasmic protein
DXA	dual-energy x-ray absorptiometry
EAA	estrogen agonist antagonist
FAK	focal adhesion kinase
FDA	US Food and Drug Administration
FGF	fibroblast growth factor
FRAX	World Health Organization fracture risk assessment tool
GFR	glomerular filtration rate
GI	gastrointestinal
GIO	glucocorticoid-induced osteoporosis
GSK-3β	glycogen synthase kinase-3β
ICTP	c-terminal telopeptide
IGF	insulin-like growth factor
IOM	Institute of Medicine

LGR4	leucine-rich repeat-containing G protein
LRP5/6	lipoprotein-receptor related protein
m-CSF	macrophage-colony stimulating factor
MMP	matrix metalloproteases
NF-Kβ	nuclear factor kappa β
NHANES	national health and nutrition examination survey
NTX	N-terminal type 1 collagen telopeptide
OCN	osteocalcin
ONJ	osteonecrosis of the jaw
OPG	osteoprotegerin
P13K	phosphatidyl inositol 3-kinase
pDXA PICP	peripheral dual-energy x-ray absorptiometryprocollagen type 1 carboxy(C)-terminal propeptide
PINP	procollagen type 1 amino(N)-terminal propeptide
PPARγ	peroxisome proliferator-activated receptor γ
PTH	parathyroid hormone
PTHrP	parathyroid hormone-related protein
QCT	quantitative computed tomography
QUS	quantitative ultrasound
RANK	receptor activator of nuclear factor-kappa β
RANKL	receptor activator of nuclear factor-kappa β ligand
RDA	recommended dietary allowances
runX2	runt-related transcription factor
Scr	nonreceptor tyrosine kinase
sFRP	secreted frizzled related proteins
TBS	trabecular bone score
TCF/LEF	T-cell-specific transcription factor 4/lymphoid enhancer factor 1

TGF-β	tissue growth factor-β
TNF-α	tumor necrosis factor-α
TRACP5b	tartrate-resistant acid phosphatase isoenzyme 5
TRPV6	transient receptor potential cation channel subfamily V member 6
TSEC	tissue selective estrogen complex
UL	upper limits
USP	United States Pharmacopeia
USPSTF	United States Preventive Services Task Force
VDR	vitamin D receptor
VFA	vertebral fracture assessment
WIFI	Wnt inhibitory factor 1
WISE	Wnt modulator insurface estoderm
WHO	World Health Organization
Wnt	wingless tail ligands

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is correct about the epidemiology of osteoporosis?

    A. The disease affects women and men equally.

    B. Vertebral fractures are the most prevalent and the largest component of osteoporosis healthcare expenditures.

    C. The disease affects all race and ethnic groups equally.

    D. Adults with low bone density also experience osteoporotic fractures.

2. Which statement is true about bone physiology and pathophysiology?

    A. Osteoblasts secrete osteoprotegerin that binds to immature and mature osteoclasts to cause bone resorption.

    B. Bone loss due to menopause is predominantly from increasing bone resorption.

    C. Parathyroid hormone prevents RANKL from binding to the Wnt signaling pathway.

    D. Sclerostin binds to RANKL and thereby stops bone formation.

3. Which statement is correct about calcium and vitamin D homeostasis?

    A. Calcium undergoes predominantly a passive absorption process from the stomach to achieve the serum calcium concentration.

   B. Vitamin D increases calcium absorption from the small intestine.

   C. Vitamin D is converted to 25(OH) vitamin D in the kidneys.

   D. Guidelines consider 25(OH) vitamin D concentrations less than 50 ng/mL (mcg/L; 125 nmol/L) to be deficient.

4. The FRAX tool can be used to calculate fracture risk in which of the below patients to determine whether osteoporosis therapy is needed or should be continued?

   A. A 68-year-old postmenopausal woman with a T-score of -2.1 at the femoral neck.

   B. A 72-year-old woman currently receiving denosumab.

   C. A 70-year-old man with a T-score of -2.7 at the femoral neck.

   D. A 58-year-old woman with a 3-year history of osteoporosis secondary to glucocorticoid therapy.

   E. A 66-year-old woman with a low-trauma vertebral fracture on abaloparatide.

5. A 65-year-old woman with osteoporosis has adjusted her diet but cannot achieve the recommended daily calcium intake. She has hypertension and hypercholesteremia. Her daily medications include alendronate, amlodipine, and atorvastatin. Her current dietary calcium intake is approximately 700 mg daily. Which of the following calcium supplement regimens is the BEST recommendation? Note doses listed represent elemental calcium content.

   A. Calcium carbonate 500 mg daily

   B. Calcium carbonate 1,200 mg daily in divided doses

   C. Calcium citrate 250 mg twice daily

   D. Calcium citrate 1,200 mg daily in divided doses

6. A 66-year-old woman with osteoporosis asks for recommendations for calcium and vitamin D daily intakes. According to the American Association of Clinical Endocrinology guidelines, which daily calcium and vitamin D intake would you recommend she achieve through diet and/or supplements?

   A. Calcium 1,000 mg and vitamin D 600 units

   B. Calcium 1,000 mg and vitamin D 800 units

   C. Calcium 1,200 mg and vitamin D 600 units

   D. Calcium 1,200 mg and vitamin D 1,000 units

   E. Calcium 1,500 mg and vitamin D 2,000 units

7. In which of the following postmenopausal women should bisphosphonate therapy be recommended? A postmenopausal woman with a

   A. T-score lumbar spine −0.9

   B. T-score lumbar spine −2.1, T-score femoral neck −1.9, and 10-year probability of major osteoporotic fracture of 12%

   C. T-score lumbar spine of −2.3 and 10-year probability of hip fracture of 3.2%

   D. T-score femoral neck of −2.3 and 10-year probability of major osteoporotic fracture of 18%

8. Which oral medication is a first-line therapy option for osteoporosis in a postmenopausal woman with high fracture risk?

A. Romosozumab

B. Alendronate

C. Ibandronate

D. Raloxifene

9. A patient with osteoporosis is being treated with alendronate to prevent hip and spine fractures. What is the minimum timeframe alendronate should be continued before considering a drug holiday for a patient with high fracture risk?

A. 1 year

B. 3 years

C. 5 years

D. 6 years

10. Which instruction for administration should be given to a patient on delayed release risedronate?

A. Take after breakfast

B. Remain upright for at least 60 minutes after taking

C. Take with at least 4–8 ounces (120–240 mL) of water

D. May take together with your multivitamin tablet

11. A health professional identifies a 70-year-old postmenopausal woman who has not refilled her risedronate prescription for the last 6 months. The practitioner discusses her adherence with her. She responds that she is concerned about osteonecrosis of the jaw (ONJ). What is the health professional's BEST response?

A. ONJ is only associated with intravenous bisphosphonate medications.

B. ONJ only happens in patients with cancer taking high-dose bisphosphonates.

C. Because of the risk of ONJ, the healthcare team will consider changing your risedronate to denosumab.

D. ONJ is rare with this medication. You are more likely to have a hip fracture.

12. A 53-year-old postmenopausal woman is in the community pharmacy participating in an osteoporosis health fair. The pharmacist calculates her FRAX scores and finds she has a 1.2% risk for hip fracture and a 14% risk for any osteoporotic fracture. She has a strong family history of breast cancer. What should the pharmacist recommend?

A. Practice a bone-healthy lifestyle and get a central DXA when your hip fracture FRAX score is greater than 3% or your major osteoporotic fracture risk is greater than 20%.

B. Since you have osteoporosis, schedule a visit with your healthcare provider to get an osteoporosis prevention medication ordered.

C. Ask your healthcare provider for a central DXA, and if you have only spine but not hip osteoporosis, raloxifene could be a good medication for you.

D. Get a central DXA in 5 years since you don't have osteoporosis.

13. A 70-year-old man with symptomatic hypogonadism is diagnosed with osteoporosis. He is at high risk for hip fracture. Which of the following is the BEST initial treatment?

A. Risedronate and testosterone

B. Ibandronate and testosterone

C. Alendronate alone

D. Ibandronate alone

E. Testosterone alone

14. A 38-year-old premenopausal woman with a 15-year history of inflammatory bowel disease for which she takes prednisone 7.5 mg daily is in clinic today to discuss her DXA results. Her Z-scores are lumbar spine −2.8 and femoral neck (right) −2.6. Besides a bone health lifestyle, what would you recommend/do today?

A. All osteoporosis medications are contraindicated, so she should add daily running to her bone healthy lifestyle.

B. Data support denosumab but not bisphosphonates to prevent fractures in premenopausal women. Denosumab has no fetal toxicity risks.

C. Add calcium and vitamin D supplements to achieve adequate intakes to prevent bone loss. They are safe during pregnancy.

D. If she uses birth control, she could start a bisphosphonate. No long-term effects exist for a future baby.

15. A 60-year-old woman is initiated on alendronate. She has been receiving prednisone for rheumatoid arthritis. She asks the pharmacist why her doctor started this medication. Your BEST answer is?

A. Because of your age but not due to your medications, the doctor prescribed alendronate to prevent postmenopausal osteoporosis.

B. The prednisone you are taking for arthritis causes bone loss and fractures that can be prevented with this medication. Bone loss also decreases with aging.

C. Your doctor should have prescribed romosozumab.

D. The osteoporosis medication is not needed.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** 43 million adults have low bone mass. In one study, 5.3% of adults with low bone mass had osteoporotic fractures, just a bit lower than the percentage of those with osteoporosis having a fracture (6.8%). Women have a higher incidence of osteoporosis; however, mortality after a hip fracture is greater in men. Non-Hispanic White and Mexican American women have more osteoporosis and osteoporotic fractures than non-Hispanic Black women. Hip fractures consume the greatest amount of osteoporosis healthcare expenditures. See the “Introduction” and “Epidemiology” sections.

2. **B.** Bone loss due to menopause is predominantly due to increased bone resorption from increased RANKL and decreased osteoprotegerin. Osteoblasts control bone resorption by producing RANKL that works to increase maturation of osteoclasts and also increase their actions on bone. They also secrete osteoprotegerin that binds to RANKL to stop bone resorption. Parathyroid hormone stimulates Wnt activity to increase bone formation. Sclerostin inhibits bone formation by binding to LRP 5/6. See “Bone Physiology” section and Fig. 112-2A-C.

3. **B.** Calcium absorption is an active process requiring 1,25(OH) vitamin D, and occurs in the duodenum and jejunum. Vitamin D is converted to 25(OH) vitamin D in the liver and to 1,25(OH) vitamin D in the kidneys. 25(OH) vitamin D concentrations greater than 30 ng/mL (mcg/L; 75 nmol/L) are usually considered in the normal range, insufficiency is usually described as 20 to 30 ng/mL (mcg/L; 50-75 nmol/L), and deficiency is usually described as less than 20 ng/mL (mcg/L; 50 nmol/L). Certain laboratories can have different cut off points, for example, deficiency less than 13 ng/mL (mcg/L; 32 nmol/L). See the “Calcium Homeostasis, Vitamin D, and Parathyroid Hormone” and “Vitamin D supplementation” sections.

4. **A.** Per US guidelines and practices, FRAX should be used to calculate fracture risk in patients with low bone mass (T-score between −1 and −2.5) to determine if prescription osteoporosis medications are needed. FRAX should not be used for patients on current therapy, who already have

osteoporosis diagnosed or if a patient has had a low-trauma fracture. See the "Risk Factor Assessment," "Diagnosis of Osteoporosis," "Drug Treatment of Choice," and "Glucocorticoid-induced Osteoporosis" sections.

5. **A.** The goal for a woman this age is 1,200 mg of calcium per day. She is receiving 700 mg through her diet, which leaves a need for 500 mg daily from supplements. This patient is not taking any acid-suppression therapy where calcium citrate would be the preferred salt since it does not require acid for absorption. The calcium citrate option here is also twice a day, increasing medication burden. Calcium carbonate is inexpensive and has a higher percentage of elemental calcium. See "Nonpharmacologic Therapy" (Calcium), "Pharmacologic Therapy" (Calcium Supplementation), and Table 112-5 sections.

6. **D.** Calcium goals are different between men and women 51 to 70 years old. For this woman, 1,200 mg elemental calcium would be recommended. The American Association of Clinical Endocrinologists recommends 1,000 to 2,000 units of vitamin D for patients with osteoporosis or at high risk for osteoporosis, which would include all older adults. The National Osteoporosis Foundation recommends 800 to 1,000 units of vitamin D daily and the Institute of Medicine recommends 600 units daily for this age group. See the "Pharmacologic Therapy" (Calcium Supplementation, Vitamin D Supplementation) sections and Table 112-5.

7. **C.** Therapy for osteoporosis is indicated for those with a low-trauma fracture, a T-score <−2.5, or low bone mass (T-score between −1 and −2.5) and a 10-year risk of major osteoporotic fracture of greater than or equal to 20% or hip fracture of greater than or equal to 3%. See the "Diagnosis of Osteoporosis" section and Fig. 112-3.

8. **B.** Medications recommended first line for treatment of osteoporosis with high fracture risk are those that reduce the risk of hip fracture. These medications include alendronate, risedronate, zoledronic acid, and denosumab. Alendronate and risedronate are orally available medications. The other medications might be used if high risk for breast cancer (raloxifene) or very high fracture risk (romosozumab). Ibandronate does not have hip fracture prevention data. See the "Pharmacologic Therapy" (Bisphosphonates, Denosumab, and Romosozumab) sections and Fig. 112-3.

9. **C.** Drug holidays are used only for bisphosphonate medications because they reside in bone for long durations after discontinuation and have some activity. For the other medication classes, bone effects begin to return to baseline after discontinuation. The minimum time at which a drug holiday from oral bisphosphonates can be considered is after 5 years of therapy. The minimum time at which a drug holiday from zoledronic acid is considered is after 3 years of therapy. The fracture risk of the patient will be considered (longer treatment durations for patients at very high risk of fracture, such as those on zoledronic acid for 6 years). See the "Pharmacologic Therapy" (Bisphosphonates) section.

10. **A.** Delayed-release risedronate is the only oral bisphosphonate that can be taken after food (breakfast). Alendronate, regular release risedronate, and ibandronate need to be taken 30 minutes before breakfast. All oral bisphosphonates should be ingested with 6 to 8 ounces (180-240 mL) of water only (oral delayed-release risedronate can be taken with 4 ounces (120 mL). Patients need to remain upright for at least 30 minutes (60 minutes for ibandronate) to prevent oral bisphosphonate gastrointestinal adverse effects. Oral bisphosphonates have minimal absorption <1%, so they should not be taken with any other medications or supplements nor with any foods or beverages except plain water. See Tables 112-7 and 112-8.

11. **D.** Osteonecrosis of the jaw (ONJ) is a rare adverse effect seen with oral and intravenous bisphosphonates, denosumab, and romosozumab but not with raloxifene and conjugated equine estrogens with bazedoxifene. In osteoporosis, the incidence is 0.001% to 0.01%. The incidence is higher with larger doses of intravenous bisphosphonates used in cancer patients (also increased from radiation and glucocorticoid therapy use) but can occur with lower oral and injectable doses for osteoporosis. Denosumab can prevent hip fractures but does have ONJ as a rare adverse effect. She might have problems with insurance coverage for denosumab, which could be explored. The magnitude of the risk of ONJ and the benefit of therapy should be conveyed to the patient to determine if it alleviates her concerns. You can use an osteoporosis decision aid to help her understand the risks. See the "Pharmacologic Therapies" (Bisphosphonates, Denosumab, Estrogen Agonists/Antagonists Mixed Estrogen Agonists/Antagonists and Tissue Selective Estrogen Complexes) sections and Tables 112-6 and 112-8.

12. **C.** A FRAX major osteoporotic fracture risk score greater than 8.4% for a postmenopausal woman under 65 years old should get a central DXA. Younger postmenopausal women are at greater risk for a vertebral fracture. With her family history of breast cancer, she could be a candidate for raloxifene as long as she does not have osteoporosis at the hip. Since her FRAX suggests a DXA, she should not wait for 5 years. With normal FRAX scores (<8.4%) and no other risks, getting a repeat DXA in 5 years could be acceptable. FRAX scores are screening data. Central DXA would be needed for a diagnosis. Practicing a bone healthy lifestyle is good for everyone including this woman, but she needs to get a DXA now. See the "Risk Factor Assessment." "Monitoring of Patient-Centered Care Plan," and "Pharmacologic Therapy" sections, Fig. 112-3, and Table 112-8.

13. **A.** If a man has both symptomatic hypogonadism and osteoporosis with a high risk of fracture, he would be prescribed both testosterone and a first line osteoporosis medication, one of the infrequent times combination therapy is advocated. The provider might start one medication first to check for tolerance and then add the next medication. Testosterone has a positive effect on bone but is generally insufficient alone to prevent osteoporosis and osteoporotic fractures. An older man has a high risk for hip fracture, requiring a first-line medication such as alendronate, risedronate, zoledronic acid, and denosumab. Ibandronate does not decrease hip fracture risk. See sections "Pathophysiology" (Male Osteoporosis), "Pharmacologic Therapy" (Hormone Therapies [Testosterone]), and (Sequential and Combination Therapy) sections.

14. **C.** This woman is categorized as low fracture risk since her Z-scores are above –3.0 and she hasn't had a fragility fracture. The American College of Rheumatology does not recommend any prescription therapy for patients on glucocorticoids with low fracture risk. Due to secondary causes or medications, premenopausal women can develop osteoporosis. Glucocorticoids are the medications that cause the most medication-induced osteoporosis. Bisphosphonates stay in bone for long durations and could have an impact on the fetus during pregnancy, so childbearing status needs to be determined and considered. If a woman does not become pregnant while on therapy and needs bone loss and fracture prevention, the benefit of a bisphosphonate or denosumab could be considered greater than the risk; however, the woman needs to be educated about all benefits, risks, and unknown fetal toxicities to make this decision about a future pregnancy. Data on osteoporosis medications for fracture prevention in children, and premenopausal and pregnant women are limited or nonexistent. Calcium and vitamin D are assumed safe during pregnancy. They have some effects on decreasing bone density. In premenopausal women, only the Z-score is evaluated and if <−2.0 she is labeled as bone mass below the expected range for age, not as having osteoporosis (unless she has had the required number of fragility fractures) per International Society of Bone Densitometry guidelines. The T-scores will be used with FRAX to determine her osteoporosis risk and medication choices. FRAX scores need to be increased by 1.15 for major osteoporotic fracture and by 1.2 for hip fracture for interpretation. (see the "Nonpharmacologic Therapy" (Calcium, Vitamin D, and Phytoestrogens), "Special Populations" (Premenopausal Women, and Glucocorticoid-Induced Osteoporosis)] sections. See Tables 112-7 and 112-8.

15. **B.** Glucocorticoids can cause bone loss, osteoporosis, and osteoporotic fractures and require osteoporosis medications to prevent these conditions. Bisphosphonates are used to prevent glucocorticoid-induced bone loss. Bisphosphonates are also used to prevent postmenopausal osteoporosis, so this medication would be used for both indications. Teriparatide has evidence to help prevent osteoporosis while on glucocorticoids but no data exist yet for romosozumab. See the "Medication-Induced Secondary Causes of Osteoporosis" and "Glucocorticoid-Induced Osteoporosis" sections

DiPiro's Pharmacotherapy: A Pathophysiologic Approach, 12e

Chapter 113: Gout and Hyperuricemia

Michelle A. Fravel; Michael E. Ernst

KEY CONCEPTS

KEY CONCEPTS

1. Treatment of hyperuricemia in the absence of a history of gout (ie, asymptomatic hyperuricemia) is not recommended.

2. An acute gout flare can be treated effectively with short courses of nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, or low-dose colchicine.

3. Initiation of a xanthine oxidase inhibitor may be considered in patients with one of the following indications for urate-lowering therapy (ULT): (a) one or more subcutaneous tophi, (b) evidence of joint damage by radiography, (c) two or more gout flares per year, (d) more than one previous gout flare but infrequent flares (less than two per year), (e) first gout flare in the presence of CKD stage 3 or greater, serum uric acid >9 mg/dL (535 μmol/L), or urolithiasis.

4. The goal serum urate concentration when using ULT is less than 6 mg/dL [357 μmol/L].

5. Allopurinol is the preferred ULT given its preferable safety and efficacy profile.

6. Uricosuric drugs have limited efficacy in patients with impaired kidney function [CKD stage 3 or greater].

7. Pegloticase should be reserved for patients in whom treatment with a xanthine oxidase inhibitor, uricosuric, and other interventions have failed to achieve the serum uric acid target, and who continue to have frequent gout flares (two or more per year) or non-resolving subcutaneous tophi.

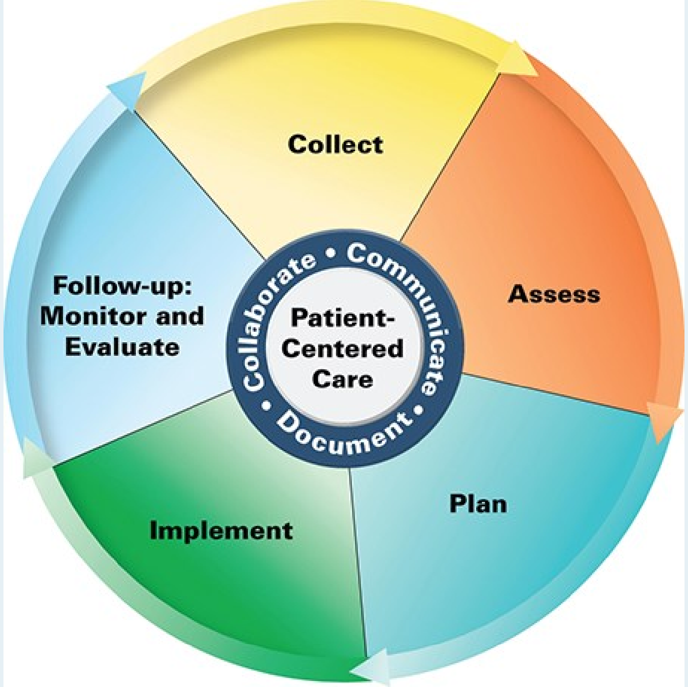
8. Low-dose colchicine, NSAID, or oral corticosteroid therapy should be administered to minimize the risk of acute gout attacks during the first 3 to 6 months of initiating ULT; therapy can be extended beyond this time period if gout flares persist.

9. Uric acid nephrolithiasis should be treated with adequate hydration (2 L/day) and 30 to 80 mEq/day (mmol/day) of potassium bicarbonate or potassium citrate.

10. Patients with hyperuricemia or a history of gouty arthritis should be evaluated for commonly associated comorbidities (eg, hypertension, diabetes, CKD, cardiovascular disease), and implement lifestyle modifications and aggressive management of risk factors (eg, weight loss, reduction of alcohol intake, control of blood pressure, glucose, and lipids).

PATIENT CARE PROCESS

Patient Care Process for Gout



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, ethnicity)
- Patient medical history (see Table 113-1)
- Dietary habits that may lead to increased uric acid concentrations, including alcohol consumption, intake of high purine foods, and products containing high-fructose corn syrup
- Current medications that may contribute to hyperuricemia (see Table 113-2)
- Subjective report of acute gout symptoms
- Objective data
    - Blood pressure (BP), height, weight
    - Labs including uric acid, serum creatinine (SCr)
    - Synovial fluid aspirate

Assess

- Presence of acute gout (see Tables 113-3 and 113-5)
- Presence of hyperuricemia (>6.8 mg/dL [404 µmol/L])
- Indication for urate-lowering therapy (see Table 113-6)
- Optimal therapy given the patient-specific characteristics (see Table 113-9)
- Presence of other cardiovascular risk factors (eg, hypertension, diabetes)

Plan[*]

- Drug therapy regimen, including a specific agent for the treatment of acute gout: dose, route, frequency, and duration (see Table 113-6)
- Monitoring parameters for efficacy (eg, resolution of pain) and safety (eg, signs and symptoms of adverse effects associated with selected therapy), frequency and timing of follow-up
- Drug therapy regimen including specific agent for treatment of hyperuricemia if indicated: dose, route, frequency, and duration (see Table 113-6)
- Patient education (eg, the purpose of treatment vs prevention, dietary and lifestyle modification, drug-specific information, medication counseling; see Table 113-6)
- Self-monitoring for resolution of gout symptoms and occurrence of medication side effects
- Referrals to other providers when appropriate (eg, rheumatologist, dietitian)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, assessment of uric acid, SCr, adherence)

Follow-up: Monitor and Evaluate

- Resolution of gout symptoms (eg, pain)
- Presence of adverse effects (eg, diarrhea [colchicine], agitation [corticosteroids], rash or allopurinol hypersensitivity syndrome [allopurinol])
- Uric acid concentrations [allopurinol, febuxostat] (adjust dose as needed to achieve uric acid <6.0 mg/dL [357 μmol/L])
- Patient adherence to treatment plan using multiple sources of information

** Collaborate with patients, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Gout and pseudogout” from Khan Academy (Available at: https://www.youtube.com/watch?app=desktop&v=1O3F-b8FfDY&list=PL5JaZVPnPe4YY4F2P50R14mjAy3gr2giX&index=11). This 10-minute video provides a brief overview of the pathophysiology of gout versus pseudogout. The video is useful to enhance student’s understanding of differences in pathophysiology and how they impact the treatment approach for each disorder, as well as the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

The term gout describes an inflammatory response to precipitation of monosodium urate (MSU) crystals in both articular and non-articular tissues.[1] The underlying metabolic disorder of gout is an elevated serum uric acid level (hyperuricemia), which is defined physiochemically as a serum that is supersaturated with monosodium urate and begins to exceed the limit of solubility (concentrations above 6.8 mg/dL [404 μmol/L]). Although hyperuricemia is fundamental to the development of gout, the mere presence of hyperuricemia itself is often an asymptomatic condition.[2,3]

EPIDEMIOLOGY

The prevalence of gout varies widely across the world, with many factors potentially contributing to the variance, including genetics, dietary habits, and socioeconomic factors.[4] Although the prevalence of gout continues to be highest in high-income countries, the overall global burden of gout has increased over the past 50 years, likely due to the aging population and increasing rates of obesity.[4,5] According to the National Health and Nutrition Examination Survey (NHANES), NHANES 2007-2016, the prevalence of gout among adults in the United States is 3.9%, corresponding to an estimated 9.2 million people.[5] Although this represents a 1.2% increase in prevalence compared with NHANES survey data from 1988 to 1994, the rate has remained stable between 2007 and 2016.[6]

Elevated serum urate concentrations are the single most important risk factor for the development of gout, and the relationship between the risk of an attack of acute gouty arthritis and serum urate concentration is linearly correlated. The 5-year cumulative risk of gout for patients with serum urate concentrations less than 7 mg/dL (416 μmol/L) is 0.6%, compared with a risk of 30.5% in those with urate concentrations exceeding 10 mg/dL (595 μmol/L).[2] Sustained elevation of serum urate is virtually essential for the development of gout; however, hyperuricemia does not always lead to gout, and many patients with hyperuricemia remain asymptomatic. For example, even in patients with severe hyperuricemia (>10 mg/dL [595 μmol/L]), fewer than 50% develop gout over a 15-year period.[3]

Gout and hyperuricemia are more common in older adults, with the highest prevalence (8.7%) observed in those 80 years of age and older, compared with just 0.7% in those between the ages of 20 and 39 years.[5] Obesity is associated with a twofold increased risk for gout.[7] Dietary and lifestyle factors linked to obesity have also been independently associated with gout. These include consumption of alcohol, sugary beverages, and red meat, along with a sedentary lifestyle.[8]

Gout affects men about 2 to 3 times more often than women in the United States; however, the impact of sex on the risk of gout and hyperuricemia varies among different ethnicities, with a risk ratio as high as 8:1 for men compared to women in Korea.[5,9] Serum uric acid concentrations in women approach those of men once menopause has occurred due to loss of estrogen-influenced uricosuria; thus, in older age groups the gap between male and female patients narrows, and approximately half of newly diagnosed cases of gout are observed in women.[10,11] Gout in men younger than 30 years of age, or in premenopausal women, may indicate an inherited enzyme defect or the presence of kidney disease.

ETIOLOGY AND PATHOPHYSIOLOGY

In humans, the production of uric acid is the terminal step in the degradation of purines (Fig. 113-1). Uric acid serves no known physiologic purpose and is a waste product. Normal uric acid concentrations are near the limits of urate solubility, because of the delicate balance that exists between the amount of urate produced and excreted.[1] Humans have higher uric acid concentrations than other mammals because they do not express the enzyme uricase, which converts uric acid into the more soluble allantoin.[1]

Gout occurs exclusively in humans in whom a miscible pool of uric acid exists. Under normal conditions, the amount of accumulated uric acid is about 1,200 mg in men and about 600 mg in women. The size of the urate pool is increased severalfold in individuals with gout. This excess accumulation may result from either overproduction or underexcretion of uric acid. Several conditions are associated with either decreased kidney clearance or an overproduction of uric acid, leading to hyperuricemia. Table 113-1 lists some of these conditions.

TABLE 113-1

Conditions Associated with Hyperuricemia

Primary gout	Obesity
Diabetic ketoacidosis	Sarcoidosis
Myeloproliferative disorders	Congestive heart failure
Lactic acidosis	Impaired kidney function
Lymphoproliferative disorders	Down syndrome
Starvation	Lead toxicity
Chronic hemolytic anemia	Hyperparathyroidism
Toxemia of pregnancy	Acute alcoholism
Pernicious anemia	Hypoparathyroidism
Glycogen storage disease type 1	Acromegaly
Psoriasis	Hypothyroidism
Hypoxanthine-guanine phosphoribosyltransferase deficiency	Phosphoribosylpyrophosphate synthetase overactivity
Polycythemia vera	Berylliosis
Kidney transplantation	

Overproduction of Uric Acid

The purines from which uric acid is produced originate from three sources: dietary purine, conversion of tissue nucleic acid into purine nucleotides, and de novo synthesis of purine bases. The purines derived from these three sources enter a common metabolic pathway leading to the production of either nucleic acid or uric acid. Under normal circumstances, uric acid may accumulate excessively if production exceeds excretion. The average human produces about 600 to 800 mg of uric acid each day. Dietary purines play an unimportant role in the generation of hyperuricemia in the absence of some derangement in purine metabolism or elimination. However, diet modifications are an important first step for patients who develop symptomatic hyperuricemia.

Several enzyme systems regulate purine metabolism. Abnormalities in these regulatory systems can result in overproduction of uric acid. Uric acid may also be overproduced as a consequence of increased breakdown of tissue nucleic acids and excessive rates of cell turnover, as observed with myeloproliferative and lymphoproliferative disorders, polycythemia vera, psoriasis, and some types of anemias. Cytotoxic medications used to treat these disorders can result in overproduction of uric acid secondary to lysis and breakdown of cellular matter.

Two enzyme abnormalities resulting in an overproduction of uric acid have been well described (Fig. 113-1). The first is an increase in the activity of phosphoribosyl pyrophosphate (PRPP) synthetase, which leads to an increased concentration of PRPP. PRPP is a key determinant of purine synthesis and uric acid production. The second is a deficiency of hypoxanthine-guanine phosphoribosyltransferase (HGPRT). HGPRT is responsible for the conversion of guanine to guanylic acid and hypoxanthine to inosinic acid. These two conversions require PRPP as the co-substrate and are important reactions involved in the synthesis of nucleic acids. A deficiency in the HGPRT enzyme leads to increased metabolism of guanine and hypoxanthine to uric acid and to more PRPP to interact with glutamine in the first step of the purine pathway.[1] Complete absence of HGPRT results in the childhood Lesch–Nyhan syndrome, characterized by choreoathetosis, spasticity, intellectual disability, and markedly excessive production of uric acid. A partial deficiency of the enzyme may be responsible for marked hyperuricemia in otherwise normal, healthy individuals.

Underexcretion of Uric Acid

Normally, uric acid does not accumulate as long as production is balanced with elimination. About two-thirds of the daily uric acid production is excreted in the urine and the remainder is eliminated through the gastrointestinal (GI) tract after enzymatic degradation by colonic bacteria.

A decline in the urinary excretion of uric acid to a concentration below the rate of production leads to hyperuricemia and an increased miscible pool of sodium urate. Almost all the urate in plasma is freely filtered across the glomerulus. The concentration of uric acid appearing in the urine is determined by multiple renal tubular transport processes in addition to the filtered load. Evidence favors a four-component model including glomerular filtration, tubular reabsorption, tubular secretion, and post-secretory reabsorption.

Approximately 90% of filtered uric acid is reabsorbed in the proximal tubule, probably by both active and passive transport mechanisms. There is a close linkage between proximal tubular sodium reabsorption and uric acid reabsorption, so conditions that enhance sodium reabsorption (eg, dehydration) also lead to increased uric acid reabsorption. The exact site of tubular secretion of uric acid has not been determined; this too involves an active transport process. Post-secretory reabsorption occurs somewhere distal to the secretory site. Table 113-2 lists the drugs that decrease renal clearance of uric acid through modification of filtered load or one of the tubular transport processes.[12] By enhancing renal urate reabsorption, insulin resistance is also associated with gout.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Acute Gouty Arthritis

General

- Gout classically presents as an acute inflammatory monoarthritis. The first metatarsophalangeal joint is often involved ("podagra"), but any joint of the lower extremity can be affected and occasionally gout will present as a monoarthritis of the wrist or finger. The spectrum of gout also includes nephrolithiasis, gouty nephropathy, and aggregated deposits of sodium urate (tophi) in cartilage, tendons, synovial membranes, and elsewhere.

Signs and Symptoms

- Fever, intense pain, erythema, warmth, swelling, and inflammation of involved joints.

Laboratory Tests

- Elevated serum uric acid concentrations; leukocytosis.

Other Diagnostic Tests

- Observation of MSU crystals in synovial fluid or a tophus.
- For patients with long-standing gout, radiographs may show asymmetric swelling within a joint on or subcortical cysts without erosions.

① Gout is diagnosed clinically by the presence of symptoms, rather than laboratory tests of uric acid. In fact, asymptomatic hyperuricemia discovered incidentally generally requires no therapy because many individuals with hyperuricemia will never experience an attack of gout.[2,3] These patients should still be encouraged to implement lifestyle measures to reduce serum urate concentrations.

Acute Gouty Arthritis

A classic acute attack of gouty arthritis is characterized by rapid and localized onset of excruciating pain, swelling, and inflammation. The attack is typically monoarticular at first, most often affecting the first metatarsophalangeal joint (great toe) and then, in order of frequency, the insteps, ankles, heels, knees, wrists, fingers, and elbows. In one-half of initial attacks, the first metatarsophalangeal joint is affected, a condition commonly referred to as podagra (Fig. 113-2). Up to 90% of patients with gout will experience podagra at some point in the course of their disease.[2]

FIGURE 113-2

Acute gout attack of the first metatarsophalangeal joint. *(Reproduced with permission from Imboden J, Hellmann DB, Stone JH. Current Rheumatology Diagnosis &Treatment. 2nd ed. New York: McGraw Hill, 2004:316.)*

Atypical presentations of gout also occur. For older adults, gout can present as a chronic polyarticular arthritis that can be confused with rheumatoid arthritis or osteoarthritis. Table 113-3 summarizes the different clinical manifestations of gout.

TABLE 113-3

Clinical Manifestations of Gout

Acute gout	Monoarticular arthritis Frequently attacks the first metatarsophalangeal joint (“podagra”), although other joints of the lower extremities are also frequently involved Affected joint is swollen, erythematous, and tender
Interval gout	Asymptomatic period between attacks
Tophaceous gout	Deposits of monosodium urate crystals in soft tissues Complications include soft tissue damage, deformity, joint destruction, and nerve compression syndromes such as carpal tunnel syndrome
Atypical gout	Polyarthritis affecting any joint, upper or lower extremity May be confused with rheumatoid arthritis or osteoarthritis
Gouty nephropathy	Nephrolithiasis Acute and chronic kidney disease

The predilection of acute gout for peripheral joints of the lower extremity is probably related to the low temperature of these joints combined with high intra-articular urate concentration. Synovial effusions are likely to occur transiently in weight-bearing joints during the course of a day with routine activity. At night, water is reabsorbed from the joint space, leaving behind a supersaturated solution of monosodium urate (MSU), which can precipitate attacks of acute arthritis. Attacks generally begin at night with the patient awakened from sleep by excruciating pain.

The development of crystal-induced inflammation involves several chemical mediators causing vasodilation, increased vascular permeability, complement activation, and chemotactic activity for polymorphonuclear leukocytes.[1] Phagocytosis of urate crystals by the leukocytes results in rapid lysis of cells and a discharge of lysosomal and proteolytic enzymes into the cytoplasm. The ensuing inflammatory reaction is associated with intense joint pain, erythema, warmth, and swelling. Fever is common, as is leukocytosis. Untreated attacks may last from 3 to 14 days before spontaneous recovery.

Although acute attacks of gouty arthritis may occur without apparent provocation, several conditions may precipitate an attack. These include stress, trauma, alcohol ingestion, infection, surgery, rapid lowering of serum uric acid by ingestion of uric acid-lowering agents, and ingestion of certain drugs known to elevate serum uric acid concentrations (Table 113-2). The natural course of an acute flare, if left untreated, varies among patients and may resolve after several hours or may take up to 2 weeks. Furthermore, acute flares of gouty arthritis may initially occur infrequently. Over time the duration of untreated attacks may become longer and the interval between attacks may shorten if appropriate measures to correct hyperuricemia are not undertaken. Later in the disease, tophaceous deposits of MSU in the skin or subcutaneous tissues may be found. These tophi are often found on the hands, wrists, elbows, or knees. It takes 10 or more years for tophi to develop.

Diagnostic Evaluation

Table 113-4 lists the differential diagnosis of gout.[10] A definitive diagnosis of gout requires aspiration of synovial fluid from the affected joint and identification of intracellular crystals of monosodium urate monohydrate in synovial fluid leukocytes.[1] Identification of MSU crystals are highly dependent on the experience of the observer. Crystals are needle-shaped, and when examined under polarizing light microscopy, they are strongly negatively birefringent (Fig. 113-3). Crystals can be observed in synovial fluid during asymptomatic periods.[13] If an affected joint is tapped, the resulting synovial fluid may have white cells and appear purulent. Such findings should always raise the question of infection. If any clinical features of infection are present, such as high fever, elevated white blood cell count, multiple joints affected, or an identified source of infection, proper diagnosis and treatment are critical. Patients with gout can have septic arthritis. Diabetes, alcohol abuse, and advanced age increase the likelihood of septic arthritis.

TABLE 113-4

Differential Diagnosis of Gout

1. Pseudogout (calcium pyrophosphate crystal-related arthritis)
2. Rheumatoid disease
3. Psoriatic arthritis
4. Osteoarthritis
5. Septic arthritis/bursitis
6. Cellulitis
7. Osteomyelitis
8. Unrelated hyperuricemia (as in psoriasis, hypertension) when joint pain is not caused by gout

In lieu of obtaining a synovial fluid sample from an affected joint to inspect for urate crystals, a clinical diagnosis may be supported by the following characteristics: monoarticular involvement of a foot or ankle joint, previous similar episode, rapid onset of severe pain and swelling (peak pain intensity in <24 hours), erythema, male sex, presence of cardiovascular disease, and hyperuricemia. However, this approach has limitations, including a failure to recognize atypical gout presentations and the fact that serum uric acid concentrations can be normal or even low during an acute gout attack.[10,14] Radiographs may show evidence of MSU crystal deposits; however, ultrasound may be more helpful in the identification of tophi or a double contour sign at cartilage surfaces, which is specific for articular urate deposits.[15] The presence of chondrocalcinosis on radiographs may indicate pseudogout (see additional discussion on pseudogout below). Table 113-5 summarizes the European League Against Rheumatism (EULAR) evidence-based diagnostic principles for gout.[15]

TABLE 113-5

EULAR Recommendations for Diagnosis of Gout

Recommendations	Level of Evidence	Grade of Evidence
1. Searching for crystals in synovial fluid or tophus aspirates is recommended in every person with suspected gout, because demonstration of MSU crystals allows a definitive diagnosis of gout.	2b	B
2. Gout should be considered in the diagnosis of any acute arthritis in an adult. When synovial fluid analysis is not feasible, a clinical diagnosis of gout is supported by the following suggestive features: monoarticular involvement of a foot (especially the first MTP) or ankle joint; previous similar acute arthritis episodes; rapid onset of severe pain and swelling (at its worst in <24 hours); erythema; male gender; and associated cardiovascular diseases and hyperuricemia. These features are highly suggestive, but not specific, for gout.	2b	B
3. Synovial fluid aspiration and examination for crystals in any patient with undiagnosed inflammatory arthritis is recommended.	3	C
4. The diagnosis of gout should not be made on the presence of hyperuricemia alone.	2a	B
5. When a clinical diagnosis of gout is uncertain and crystal identification is not possible, patients should be investigated with imaging (see #6 below) to search for MSU crystal deposition and features of any alternative diagnosis.	1b	A
6. Plain radiographs are indicated to search for imaging evidence of MSU crystal deposition but have limited value for the diagnosis of gout flare. Ultrasound scanning can be more helpful in establishing a diagnosis in patients with suspected gout flare or chronic gouty arthritis by detection of tophi not evident on clinical examination, or a double contour sign at cartilage surfaces, which is highly specific for urate deposits in joints.	1b	A
7. Risk factors for chronic hyperuricemia should be searched for in every person with gout; these include chronic kidney disease; obesity, medications (including diuretics, low-dose aspirin, cyclosporine, tacrolimus); excess consumption of alcohol (particularly beer and spirits), non-diet sodas, red meat, and shellfish.	1a	A
8. Systematic assessment for the presence of associated comorbidities in people with gout is recommended, including obesity, kidney disease, hypertension, ischemic heart disease, heart failure, diabetes, and dyslipidemia.	1a	A

EULAR, The European League Against Rheumatism; MSU, monosodium urate.

Data from Reference 20.

Level of Evidence: 1A = meta-analysis of cohort studies, 1B = meta-analysis of case-control studies, 2A = cohort studies, 2B = case-control studies, 3 = non-comparative descriptive studies, 4 = expert option.

Grade of Evidence: A = category 1 evidence, B = category 2 evidence or extrapolated recommendations from category 1 evidence, C = category 3 evidence or extrapolated recommendations from category 2 evidence, D = category 4 evidence or extrapolated recommendations from category 3 evidence.

The American College of Rheumatology (ACR) and EULAR have also jointly developed recommendations for the classification of gout to assist in identifying subjects potentially eligible for enrollment into clinical trials of gout treatments.[16] Although it is specifically stated that the recommendations should not be used clinically to diagnose gout, the classification system may be a useful reference when evaluating a patient presenting with symptoms suggestive of gout. The recommendations utilize a point-based system that incorporates clinical, laboratory, and imaging information, which can be used when a patient presents with at least one episode of swelling, pain, or tenderness in a peripheral joint or bursa but has no evidence of MSU crystals. An online calculator is available at http://goutclassificationcalculator.auckland.ac.nz/.

Other crystal-induced arthropathies that may resemble gout on clinical presentation are caused by calcium hydroxyapatite crystals and calcium pyrophosphate dihydrate crystals (calcium pyrophosphate deposition disease [CPDD] or "pseudogout"), which are associated with calcific periarthritis, tendinitis, and arthritis.[17-19] Pseudogout is relatively common, occurring in up to 7% of all adults in Europe and the United States. Furthermore, its prevalence increases with age, doubling with every decade over 60 years.[17] Identification of calcium pyrophosphate crystals in the synovial fluid of an affected joint in combination with positive radiology findings (eg, chondrocalcinosis, hook-like osteophytes, and axial skeletal involvement) are key methods used for diagnosis of pseudogout. Importantly, calcium pyrophosphate crystals differ from uric acid crystals in that they are positively birefringent when exposed to light microscopy. Furthermore, the clinical picture may provide clues as pseudogout rarely presents with podagra and more commonly affects the knee or wrist. Although initial management of an acute flare of pseudogout is similar to the approach used for treatment of gout, management of chronic pseudogout may require use of hydroxychloroquine, methotrexate, and, ultimately, joint replacement. Recommended therapies used to prevent gout by lowering uric acid will not impact the progression of pseudogout. For these reasons, differentiating between pseudogout and gout, although challenging, is important to insure successful clinical outcomes.

Uric Acid Nephrolithiasis

Clinicians should be suspicious of hyperuricemic states in patients who present with kidney stones, as nephrolithiasis occurs in approximately 14% of patients with gout.[20] The frequency of urolithiasis depends on serum uric acid concentrations, acidity of the urine, and urinary uric acid concentration. Typically, patients with uric acid nephrolithiasis have a urinary pH of less than 6 and frequently less than 5.5. When acidic urine is saturated with uric acid, spontaneous precipitation of stones may occur.

Other factors that predispose individuals to uric acid nephrolithiasis include excessive urinary excretion of uric acid and highly concentrated urine. In addition to pure uric acid stones, hyperuricosuric individuals are at increased risk for mixed uric acid–calcium oxalate stones and pure calcium oxalate stones.

Gouty Nephropathy

There are two types of gouty nephropathy: acute uric acid nephropathy and chronic urate nephropathy.[21] In acute uric acid nephropathy, acute kidney injury occurs as a result of blockage of urine flow secondary to massive precipitation of uric acid crystals in the collecting ducts and ureters. This syndrome is a known complication for patients with myeloproliferative or lymphoproliferative disorders and is a result of massive malignant cell turnover, particularly after initiation of chemotherapy.

Chronic urate nephropathy is caused by the long-term deposition of urate crystals in the renal parenchyma. Microtophi may form, with a surrounding giant-cell inflammatory reaction. A decrease in the kidneys' ability to concentrate urine and the presence of proteinuria may be the earliest pathophysiologic disturbances. Hypertension and nephrosclerosis are common associated findings. Although kidney failure occurs in a higher percentage of gouty patients than expected, it is not clear if hyperuricemia per se has a harmful effect on the kidneys. The chronic kidney disease seen in individuals with gout may result largely from the coexistence of hypertension, diabetes mellitus, and atherosclerosis.

Tophaceous Gout

Tophi (urate deposits) are uncommon in the general population of patients with gout, but are a late complication of untreated hyperuricemia. The most common sites of tophaceous deposits for patients with recurrent acute gouty arthritis are the base of the fingers, olecranon bursae, ulnar aspect of the forearm, Achilles tendon, knees, wrists, and hands (Fig. 113-4).[21] Eventually, even the hips, shoulders, and spine may be affected. In addition to causing obvious deformities, tophi may damage surrounding soft tissue, cause joint destruction and pain, and can even lead to nerve compression syndromes including carpal tunnel syndrome.

FIGURE 113-4

TREATMENT

Desired Outcomes

The goals in the treatment of gout are to terminate the acute attack, prevent recurrent attacks of gouty arthritis, and prevent complications associated with chronic deposition of urate crystals in joints and tissues. These can be accomplished through a combination of pharmacologic and nonpharmacologic methods, including focused patient education efforts. Several organizations, including ACR, EULAR, and the American College of Physicians, have developed guidelines for the management of gout.

The first-ever ACR evidence- and consensus-based guidelines for the management of gout were published in 2012 and were most updated in 2020.[22-24] These guidelines provide specific recommendations for treatment of acute gout attacks, management of hyperuricemia in gout, and anti-inflammatory prophylaxis of acute gout during initiation of ULT. Tables 113-6 and 113-7 summarize dosing and monitoring information for available pharmacotherapy used in management and prevention of gout.

TABLE 113-6

Pharmacotherapy of Acute Gout, Anti-Inflammatory Prophylaxis During Initiation of Urate-Lowering Therapy and Hyperuricemia in Gout[a]

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Acute Gout					
NSAIDs					In general, not recommended in patients with advanced kidney disease as NSAID use may decrease kidney function; use with caution in patients with mild to moderate kidney impairment Use caution in patients taking anticoagulants given increased bleeding risk when used in combination with NSAIDs Use caution in patients with heart failure as NSAIDs can contribute to fluid retention leading to increased risk of heart
Etodolac	Lodine, various	300 mg twice daily	300-500 mg twice daily		
Fenoprofen	Nalfon, various	400 mg three times daily	400-600 mg three to four times daily		
Ibuprofen	Advil, various	400 mg three times daily	400-800 mg three to four times daily		
Indomethacin	Indocin	50 mg three times daily	50 mg three times daily initially until pain is tolerable then rapidly reduce to complete cessation		

					failure exacerbation
Ketoprofen	Orudis, various	75 mg three times daily or 50 mg four times daily	50-75 mg three to four times daily	Severe kidney impairment (GFR <25 mL/min [0.42 mL/s]): 100 mg maximum daily dose Mildly impaired kidney function: 150 mg maximum daily dose Impaired liver function with serum albumin <3.5 g/dL (35 g/L): 100 mg maximum daily dose	
Naproxen	Naprosyn, various	750 mg followed by 250 mg every 8 hours until the attack has subsided		Not recommended in severe kidney impairment (creatinine clearance <30 mL/min [0.5 mL/s])	
Piroxicam	Feldene	20 mg once daily or divided twice daily			
Sulindac	Clinoril	200 mg twice a day	150-200 mg twice daily for 7-10 days		
Meloxicam	Mobic	5 mg daily	7.5-15 mg daily	Not recommended if creatinine clearance <15 mL/min (0.25 mL/s)	
Celecoxib	Celebrex	800 mg followed by 400 mg on day one then 400 mg twice daily for 1 week			Option for patients with GI contraindications to nonselective NSAIDs; unclear risk-to-benefit ratio now due to cardiovascular concerns

Colchicine	Colcrys	1.2 mg initially, followed by 0.6 mg 1 hour later, with ongoing anti-inflammatory therapy until the flare resolves		See Table 113-8	Dose adjustment recommended when used with selected CYP3A4 and P-glycoprotein inhibitors
Corticosteroids					
Oral		0.5 mg/kg prednisone equivalent daily for 5-10 days followed by discontinuation or 0.5 mg/kg daily for 2-5 days followed by tapering for 7-10 days	30-60 mg prednisone equivalent once daily for 3-5 days, then taper in 5-mg decrements spread over 10-14 days until discontinuation		The use of an oral methylprednisolone dose pack may be considered
Intramuscular		Triamcinolone acetonide 60 mg IM once; methylprednisolone 100 mg IM once	Triamcinolone acetonide 60 mg IM once; methylprednisolone 100-150 mg IM daily for 1-2 days		Administration of intramuscular triamcinolone is to be followed by oral prednisone or prednisolone
Intra-articular	Kenalog	Triamcinolone acetonide 10 mg (large joints), 5 mg (small joints)	Triamcinolone acetonide 10-40 mg (large joints), 5-20 mg (small joints)		Intra-articular administration is acceptable when only one to two joints involved and should be used in combination with NSAIDs, colchicine, or oral corticosteroids
Corticotropin	H.P. Acthar Gel	20-40 units IM or SC	Dose may be repeated as clinically indicated; a dose of 40-80 units every 24-72 hours is used for other inflammatory conditions		Contraindicated for IV administration
Interleukin-1 inhibitors					Reserve use for refractory cases
Anakinra	Kineret	100 mg SC daily for 5 days			
Canakinumab	Ilaris	Single dose 150 mg SC			

Anti-Inflammatory Prophylaxis During Initiation of Urate-Lowering Therapy					
NSAIDs			Lowest effective dosage		
Colchicine	Colcrys	0.6 mg daily	0.6 mg once or twice daily	See Table 113-8	
Prednisone or prednisolone		≤10 mg daily			
Interleukin-1 inhibitors					Reserve use for refractory cases Studied for 16-week duration
Rilonacept	Arcalyst	320 mg loading dose followed by 160 mg weekly (SC)			
Canakinumab	Ilaris	Single SC dose (50 mg-300 mg) or four times weekly SC dosing (50 mg—50 mg—25 mg—25 mg)			
Hyperuricemia in Gout					
Xanthine oxidase inhibitors					
Allopurinol	Lopurin, Zyloprim	100 mg daily	100-800 mg daily to achieve serum urate concentration <6 mg/dL (357 µmol/L)	Start at dose of 50 mg daily for patients with a glomerular filtration rate <30 mL/min/1.73 m^2 (0.29 mL/s/m^2)	
Febuxostat	Uloric	40 mg daily	40-80 mg/daily	No dosage adjustment necessary for patients with mild-moderate kidney impairment (creatinine clearance 30-89 mL/min [0.5-1.49 mL/s])	

				Insufficient data in patients with creatinine clearance <30 mL/min (0.5 mL/s)	
Uricosurics					
Probenecid	Probalan	250 mg twice daily for 1 week	500-2,000 mg/day (target serum urate concentration <6 mg/dL [357 mol/L])	Not recommended if creatinine clearance <50 mL/min (0.83 mL/s)	
Lesinurad	Zurampic	200 mg once daily in combination with a xanthine oxidase inhibitor		Not recommended if creatinine clearance <45 mL/min (0.75 mL/s) Not studied in patients with severe hepatic disease Contraindicated in tumor lysis syndrome and Lesch-Nyhan syndrome	Should be used in combination with a xanthine oxidase inhibitor due to increased risk of acute kidney injury with lesinurad monotherapy Use is not recommended in patients taking allopurinol doses <300 mg daily (normal kidney function) or <200 mg daily (creatinine clearance <60 mL/min [1 mL/s]) Not currently marketed in the United States
Combination Therapy					
Lesinurad/Allopurinol	Duzallo	Lesinurad 200 mg/allopurinol 300 mg: one tablet daily		Lesinurad 200 mg/allopurinol 200 mg: one tablet daily recommended if creatinine clearance is 45-60 mL/min (0.75-1 mL/s) Not recommended if creatinine clearance <45 mL/min (0.75 mL/s)	See above for lesinurad and allopurinol comments Not currently marketed in the United States

Other					
Pegloticase	Krystexxa	8 mg IV every 2 weeks			Optimal treatment duration has not been established Reserved for patients with refractory gout who have failed other therapies and continue to have frequent gout flares (≥2 flares/year) OR who have non-resolving subcutaneous tophi

[a]Agents available in the United States.

CYP, cytochrome P; GFR, glomerular filtration rate; IM, intramuscular; IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug; SC, subcutaneous.

TABLE 113-7

Drug Monitoring

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
NSAIDs	Impaired kidney function (acute and chronic) gastritis (worse with concurrent aspirin), fluid retention, blood pressure elevation	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis Toxic Blood pressure Kidney function Edema Dark stools	Avoid in patients with peptic ulcer disease, active bleeding Use caution in heart failure, dehydration, impaired kidney function Consider coadministration with a proton-pump inhibitor when used long term for patients at risk for GI bleeding
Systemic corticosteroids	GI upset, increased appetite, nervousness/restlessness, transient glucose intolerance, fluid retention, blood pressure elevation	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis Toxic Glucose levels in patients with diabetes	Limit duration of therapy in patients with diabetes
Intra-articular corticosteroids	Injection pain, rebound arthritis	Therapeutic Resolution of pain Toxic Signs of rebound	Avoid if joint sepsis cannot be ruled out

		arthritis (pain relief followed by reemergence of pain)	
Corticotropin	Increased appetite, nervousness/restlessness, transient glucose intolerance, fluid retention, blood pressure elevation	Therapeutic Resolution of pain	Requires intact pituitary–adrenal axis Less effective for patients receiving long-term oral corticosteroid therapy
Colchicine	Dose-dependent GI adverse effects (diarrhea, nausea, vomiting), rare myelosuppression, and reversible neuromyopathy	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis Toxic GI symptoms Complete blood count	
Interleukin-1 inhibitors	Injection site reaction, neutropenia, immune hypersensitivity reaction, infectious disease, malignancy	Therapeutic Resolution of pain Avoidance of gout attacks when used for prophylaxis Toxic Neutrophil count (prior to initiation, monthly for the first 3 months of therapy then after 6, 9, and 12 months of therapy) Temperature (periodically to detect infection)	Safety for use in acute gout and gout prophylaxis during initiation of urate-lowering therapy has not yet been established; not FDA-approved for use in gout
Allopurinol	Rash, potential for fatal hypersensitivity syndrome	Therapeutic Serum urate level Reduced frequency of gout attacks Toxic Rash Kidney function	Testing for the HLA–B*5801 allele prior to starting allopurinol is recommended for patients of Southeast Asian (eg, Han Chinese, Korean, Thai) and African descent
Febuxostat	Liver enzyme elevation, nausea, arthralgias, and rash	Therapeutic Serum urate level Reduced frequency of gout attacks Toxic Liver function tests	Use not recommended in patients with cardiovascular disease

		Kidney function	
Probenecid	Urolithiasis	Therapeutic Serum urate level Reduced frequency of gout attacks Toxic Kidney function	Avoid in patients with CKD (stage 3 or greater)
Pegloticase	Acute gout attack during treatment initiation, anaphylaxis, GI symptoms (constipation, nausea, vomiting), chest pain, nasopharyngitis	Therapeutic Serum urate levels Reduced frequency of gout attacks Toxic Signs/symptoms of anaphylaxis following infusion	Reserved for patients with severe gout refractory to conventional therapies
Lesinurad	Acute gout attack during treatment initiation, headache, GERD, major adverse cardiovascular events have been observed although a causal relationship has not been established	Therapeutic Serum urate levels Reduced frequency of gout attacks Toxic Kidney function	Reserved for patients with hyperuricemia associated with gout who do not achieve target serum uric acid levels with conventional therapies Can be used in both urate overproduction and urate underexcretion Must be used in combination with a xanthine oxidase inhibitor due to increased risk of acute kidney injury with monotherapy Not currently marketed in the United States

FDA, Food and Drug Administration; GERD, gastroesophageal reflux disease; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; CKD, chronic kidney disease.

General Approach to Treatment

Treatment of gout can be separated into three categories: (1) treatment of the pain and inflammation associated with an acute gout attack, (2) use of ULT to prevent recurrence of future gout attacks, and (3) use of anti-inflammatory prophylaxis to prevent acute gout attacks during initiation of urate-lowering therapy, which can occur paradoxically as a result of the rapid decline in serum urate after initiation of these therapies. Each of these categories will be covered in further detail throughout the remainder of the treatment section of this chapter.

Acute Gouty Arthritis

Nonpharmacologic Therapy

Nonpharmacologic therapies have an important role in modifying the underlying hyperuricemia and reducing the risk of an acute gout attack before one occurs. However, nonpharmacologic therapies for treatment of an acute gout attack are limited and are recommended strictly as adjuvants.

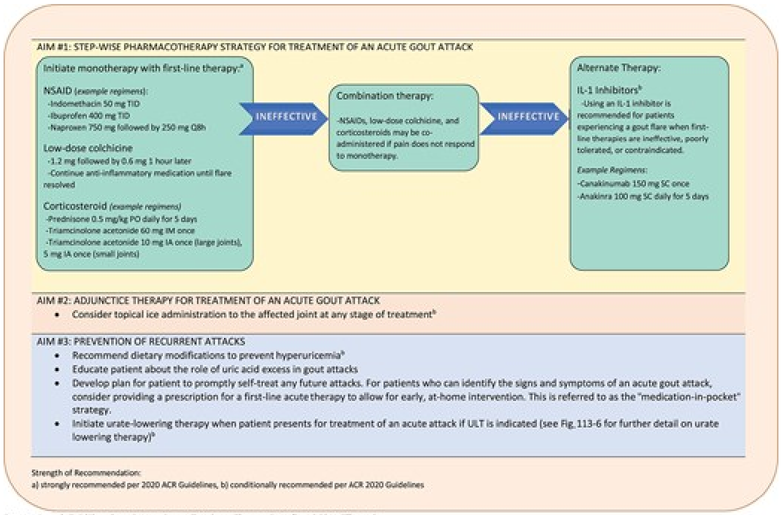
Local ice application to the affected joint is the most effective adjuvant.[24] Localized ice application results in significantly greater pain reduction in those receiving the therapy compared with those not treated with ice.[25] Complementary and alternative medicines, including vitamin C, flaxseed, cherry, and celery root, are not recommended for treatment of acute gout due to unproven benefit.[23,24]

Pharmacologic Therapy

② For most patients, acute attacks of gouty arthritis may be treated successfully with NSAIDs, corticosteroids, or colchicine. The ACR guidelines recognize these three monotherapies equally as first-line treatments of acute gout.[23,24,26,27] Treatment should commence as soon as possible after the onset of an attack. In more severe cases involving inadequate response to first-line therapy, combination first-line therapy or off-label use of IL-1 inhibitor therapy may be considered (Fig. 113-5).[23,26]

FIGURE 113-5

Comprehensive management of an acute gout attack. (IM, intramuscular; IA, intra-articular; SC, subcutaneous.) *(Data from FitzGerald JD, Dalbeth N, Mikuls TB, 2020 American College of Rheumatology Guideline for the Management of Gout. Arthritis Care Res. 72:744–760.)*



AIM #1: STEP-WISE PHARMACOTHERAPY STRATEGY FOR TREATMENT OF AN ACUTE GOUT ATTACK

Initiate monotherapy with first-line therapy:[a]

NSAID *(example regimens)*:
-Indomethacin 50 mg TID
-Ibuprofen 400 mg TID
-Naproxen 750 mg followed by 250 mg Q8h

Low-dose colchicine
-1.2 mg followed by 0.6 mg 1 hour later
-Continue anti-inflammatory medication until flare resolved

Corticosteroid *(example regimens)*
-Prednisone 0.5 mg/kg PO daily for 5 days
-Triamcinolone acetonide 60 mg IM once
-Triamcinolone acetonide 10 mg IA once (large joints), 5 mg IA once (small joints)

Combination therapy:

-NSAIDs, low-dose colchicine, and corticosteroids may be co-administered if pain does not respond to monotherapy.

Alternate Therapy:

IL-1 Inhibitors[b]
-Using an IL-1 inhibitor is recommended for patients experiencing a gout flare when first-line therapies are ineffective, poorly tolerated, or contraindicated.

Example Regimens:
-Canakinumab 150 mg SC once
-Anakinra 100 mg SC daily for 5 days

AIM #2: ADJUNCTICE THERAPY FOR TREATMENT OF AN ACUTE GOUT ATTACK
- Consider topical ice administration to the affected joint at any stage of treatment[b]

AIM #3: PREVENTION OF RECURRENT ATTACKS
- Recommend dietary modifications to prevent hyperuricemia[b]
- Educate patient about the role of uric acid excess in gout attacks
- Develop plan for patient to promptly self-treat any future attacks. For patients who can identify the signs and symptoms of an acute gout attack, consider providing a prescription for a first-line acute therapy to allow for early, at-home intervention. This is referred to as the "medication-in-pocket" strategy.
- Initiate urate-lowering therapy when patient presents for treatment of an acute attack if ULT is indicated (see Fig. 113-6 for further detail on urate lowering therapy)[b]

Strength of Recommendation:
a) strongly recommended per 2020 ACR Guidelines, b) conditionally recommended per ACR 2020 Guidelines

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are a mainstay of therapy for acute attacks of gouty arthritis because of their excellent efficacy and minimal toxicity with short-term use. Indomethacin has been historically favored as the NSAID of choice for acute gout flares, but there is little evidence to support one NSAID as being more efficacious than another. Three agents (indomethacin, naproxen, and sulindac) have US Food and Drug Administration (FDA)-approved labeling for the treatment of gout, although several others are likely to be effective.[23] The most important determinant of therapeutic success is not which NSAID is chosen, but rather, how soon it is initiated. Early initiation of treatment is more likely to be effective than if delayed; therefore, ensuring patients have a plan to access therapy on their own when needed (referred to as the "medication-in-pocket" strategy) is an important cornerstone of an optimized gout management strategy.[24] Following resolution of the attack, tapering of NSAID therapy may be considered, especially in patients with comorbidities such as impaired hepatic or kidney function where prolonged therapy would be undesirable.[23] Resolution of an acute attack for most patients generally occurs within 5 to 8 days after initiating therapy.

All NSAIDs have the potential to cause similar adverse effects. The most common areas affected include the gastrointestinal (GI) system (gastritis, bleeding, perforation), kidneys (renal papillary necrosis, reduced glomerular filtration rate), cardiovascular system (sodium and fluid retention, increased blood pressure), and central nervous system (CNS) (impaired cognitive function, headache, dizziness). Caution should be exercised when using NSAIDs in individuals with a history of peptic ulcer disease, congestive heart failure, uncontrolled hypertension, impaired kidney function, coronary artery disease, or who are concurrently receiving anticoagulants or antiplatelets. Patients with active peptic ulcer disease, decompensated congestive heart failure, chronic kidney disease, or a history of hypersensitivity to aspirin or other NSAIDs should not be prescribed an NSAID.

Selective cyclooxygenase-2 (COX-2) inhibitors present a potentially less risky alternative to nonselective NSAIDs in patients with GI issues.[28] Specific COX-2 inhibitors, etoricoxib and lumiracoxib, have demonstrated efficacy in the treatment of acute gout; however, these agents are not available in the United States. The effectiveness of high-dose celecoxib (1,200 mg on day 1 followed by 400 mg twice daily thereafter) in the treatment of acute gout has been established, but concerns regarding the cardiovascular risk of COX-2 inhibitors must be considered when using these agents (see Chapter 110, Osteoarthritis, for further discussion of COX-2 inhibitors).[29]

Corticosteroids

Corticosteroids have historically been reserved for treatment of acute gout flares when contraindications to other therapies exist, largely due to lack of evidence from controlled clinical trials. However, evidence indicates that corticosteroids are equivalent to NSAIDs in the treatment of acute gout flares.[30,31] They can be used either systemically or by intra-articular injection. With systemic therapy, a hypothetical risk exists for a rebound attack upon steroid withdrawal; therefore, gradual tapering is often employed when discontinuing. Examples of appropriate tapers include 0.5 mg/kg daily for 5 to 10 days followed by abrupt discontinuation, 0.5 mg/kg daily for 2 to 5 days followed by tapering for 7 to 10 days, or using a methylprednisolone dose pack—a 6-day regimen that starts with 24 mg on day 1 and decreases by 4 mg each day.[23]

Intra-articular administration of triamcinolone acetonide in a dose of 20 to 40 mg may be useful in treating acute gout limited to one or two joints. Injection should be done under an aseptic technique in a joint determined not to be infected. A single intramuscular injection of a long-acting corticosteroid, such as methylprednisolone, followed by a short course of oral corticosteroid therapy is another recognized therapeutic approach to the treatment of acute gout.[23] Alternatively, intramuscular corticosteroid monotherapy could be considered in patients with multiple affected joints who are unable to take oral therapy.

The adverse effects of corticosteroids are generally dose and duration dependent. Short-term use for treatment of acute attacks is generally well tolerated. Corticosteroids should be used with caution for patients with diabetes as they can increase blood sugar. In addition, patients with a history of GI problems, bleeding disorders, cardiovascular disease, and psychiatric disorders should be monitored closely for exacerbation of these conditions. Long-term corticosteroid use should be avoided because of the increased risk for osteoporosis, hypothalamic–pituitary axis suppression, cataracts, and muscle deconditioning.

Corticotropin, or adrenocorticotropic hormone (ACTH), which stimulates the adrenal cortex to produce cortisol and corticosterone, can be administered to treat acute gout. A dose of 25 to 40 international units given subcutaneously and repeated as needed has been recommended in the past for treatment of acute gout.[23] Studies with ACTH are limited, but it provides similar efficacy to systemic anti-inflammatory doses of corticosteroids.[32] Unfortunately, access to ACTH has been impacted following changes in the manufacturer of ACTH in 2007. This change in ownership resulted in a dramatic increase in the price of the medication such that it is no longer a viable treatment option.[33] The ACR guidelines support use of other first-line agents over ACTH primarily due to reduced cost effectiveness with ACTH.[24]

Colchicine

Colchicine is an antimitotic drug that is highly effective at relieving acute attacks of gout.[34] When begun within the first 24 hours of an acute attack, colchicine produces a response in two-thirds of patients within hours of administration.[35] Although it is highly effective, oral colchicine can cause dose-dependent GI adverse effects, including nausea, vomiting, and diarrhea. Other important non-GI adverse effects include neutropenia and axonal neuromyopathy, which may be worsened for patients taking other myopathic drugs such as β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) or for those with impaired kidney function.

Colchicine was used for many years to treat acute gouty arthritis, but as an unapproved drug without having undergone formal FDA review for safety and efficacy. In 2009, the FDA-approved a 0.6-mg tablet of colchicine (under the brand name Colcrys®) for oral use, which was followed by an order for all unapproved colchicine products to stop manufacturing within 90 days. Following enforcement of market exclusivity for the branded colchicine product, use of colchicine to treat acute gouty arthritis declined immediately thereafter due to the significant cost.[36] Colchicine is now once again available generically; however, increased cost remains a potential barrier given the unique patent agreements established which may reduce competition among generic producers until 2029.[37]

One benefit of the 2009 FDA approval of Colcrys® was new information on dosing. A substantially lower dose of colchicine (1.2 mg initially, followed by a single 0.6 mg dose 1 hour later) is as effective as traditionally used higher doses (continued hourly dosing until symptoms subside or GI symptoms become intolerable).[38] In addition to the low-dose regimen, the ACR guidelines also suggest that following the low-dose colchicine regimen, anti-inflammatory medication may be continued until the flare resolves.[24] This off-label dosing recommendation is based upon pharmacokinetic data that suggest that colchicine concentrations begin to decline 12 hours after administration.[38]

Postmarketing safety information suggests an increased risk of adverse events for patients receiving colchicine administered concurrently with P-glycoprotein or cytochrome P450 3A4 inhibitors (eg, clarithromycin or cyclosporine) (Table 113-8).[39] These interactions are thought to result in an increased colchicine concentration. Colchicine should also be used carefully for patients with impaired kidney and hepatic function. Colchicine dosing recommendations in these special situations are listed in Table 113-8.

TABLE 113-8

Colchicine Dosing in Special Situations/Colchicine Drug Interactions

	Treatment of Acute Gout Flares	**Prophylaxis of Gout Flares**
Impaired Kidney Function[a]		
Mild/moderate (creatinine clearance = 30-80 mL/min [0.5-1.33 mL/s])	Dose adjustment not required	Dose adjustment not required
Severe (creatinine clearance <30 mL/min [0.5 mL/s])	Dose adjustment not required; treatment course should be repeated no more than once every 2 weeks	0.3 mg daily (starting dose)
Dialysis	Single 0.6 mg dose; treatment course should not be repeated more than once every 2 weeks	0.3 mg twice weekly (starting dose)
Hepatic Impairment[b]		
Mild/moderate	Dose adjustment not required	Dose adjustment not required
Severe	Dose adjustment not required; treatment course should be repeated no more than once every 2 weeks	Dose reduction should be considered
Colchicine Drug Interactions		
Strong CYP3A4 inhibitors • Atazanavir • Clarithromycin • Darunavir/ritonavir • Indinavir • Itraconazole • Ketoconazole • Lopinavir/ritonavir • Nefazodone	Single 0.6 mg dose followed by 0.3 mg 1 hour later; dose to be repeated no earlier than 3 days	0.3 mg once every other day to 0.3 mg once daily

• Nelfinavir • Ritonavir • Saquinavir • Telithromycin • Tipranavir/ritonavir		
Moderate CYP3A4 inhibitors	Single 1.2 mg dose; dose to be repeated no earlier than 3 days	0.3 g-0.6 mg daily (0.6 mg dose may be given as 0.3 mg twice daily)
• Amprenavir • Aprepitant • Diltiazem • Erythromycin • Fluconazole • Fosamprenavir • Grapefruit juice and related citrus products • Verapamil		
P-glycoprotein inhibitors	Single 0.6 mg dose; dose to be repeated no earlier than 3 days	0.3 mg once every other day to 0.3 mg once daily
• Cyclosporine • Ranolazine		

[a] Treatment of gout flares with colchicine is not recommended in patients with impaired kidney function who are receiving colchicine for prophylaxis.

[b] Treatment of gout flares with colchicine is not recommended in patients with hepatic impairment who are receiving colchicine for prophylaxis.

Management of Hyperuricemia in Gout

Nonpharmacologic Therapy

Following treatment and resolution of an acute gout attack, the focus should shift to the prevention of future episodes. Recurrent gout attacks can be prevented by maintaining low uric acid concentrations. Although both nonpharmacologic and pharmacologic efforts to maintain low uric acid concentrations are critical in the management of gout, nonadherence with ULT is common.[40] A likely explanation for this lack in patient adherence is the silent nature of intercritical gout (the period of time between two gout attacks). Patient education, therefore, is a critical first step in the management of hyperuricemia.[24] Education should address the recurrent nature of the disease and reinforce the objective of each lifestyle/dietary modification and medication therapy recommended.

Weight loss through caloric restriction and exercise should be promoted in all patients with gout and hyperuricemia who are overweight/obese, as this may enhance renal excretion of urate.[24] Specifically, the urate-lowering effect of the DASH diet (Dietary Approaches to Stop Hypertension) has been examined. This diet includes vegetables, fruits, whole grains, reduced-fat dairy, lean meats, beans, and nuts along with avoidance of foods high in saturated fats and sweetened beverages/foods. Studies have demonstrated a reduction of ~1.0 mg/dL (~60 µmol/L) in serum uric acid levels in patients with hyperuricemia who adhere to the diet.[41,42] Restriction of alcohol intake can also aid in the management of gout, as increased alcohol consumption has been associated with an increased risk of gout attacks.[43,44] Acute ingestions of alcohol cause lactic acidemia, which reduces renal urate excretion, and long-term alcohol intake promotes production of purines as a by-product of the conversion of acetate to acetyl coenzyme A in the metabolism of alcohol.[45] The ACR guidelines conditionally recommend limiting alcohol use in all gout patients.[24] The guidelines also conditionally recommend limiting consumption of high-fructose corn syrup and purine-rich foods (organ meats and some seafood), which have also been linked to uric acid elevation.

Consumption of cherry-containing products, such as cherries and tart cherry extract, has received considerable attention and a wide variety of non-FDA-regulated supplements purporting benefits for gout are available. Uric acid lowering associated with cherry consumption has been demonstrated, although a physiologic mechanism for this effect has not been described.[46] For example, cherry intake over a 2-day period was associated with a 35% lower risk of gout attacks compared with no intake.[47] Randomized controlled trials are needed to better establish the role of cherry products before they can be recommended for management of hyperuricemia. Furthermore, the caloric and sugar content of each cherry-containing product should be considered. Since many patients with hyperuricemia can benefit from weight loss, use of these caloric-dense products is not optimal.

Another strategy to lower uric acid before initiating urate-lowering pharmacotherapy is to evaluate the patient's medication list for potentially unnecessary drugs that may elevate uric acid concentrations. Additionally, when clinically appropriate, medications that increase serum uric acid levels may be switched to equally effective medications without this effect (Table 113-2). Although the presence of gout is not an absolute contraindication to the use of thiazide diuretics in hypertensive patients, the ACR guidelines conditionally recommend that hydrochlorothiazide, specifically, be switched to an alternative antihypertensive medication when feasible.[24] This is particularly important if the patient has had frequent gout attacks or continues to have an elevated serum uric acid concentration despite appropriate therapy for gout. Importantly, the ACR guidelines specifically highlight the importance of continuing low-dose aspirin when used for an appropriate indication in patients with gout, despite its uric acid elevating properties.[24]

Pharmacologic Therapy

After the first attack of acute gouty arthritis, a decision to institute prophylactic urate-lowering pharmacotherapy may be considered. This decision should carefully balance risk and benefit.

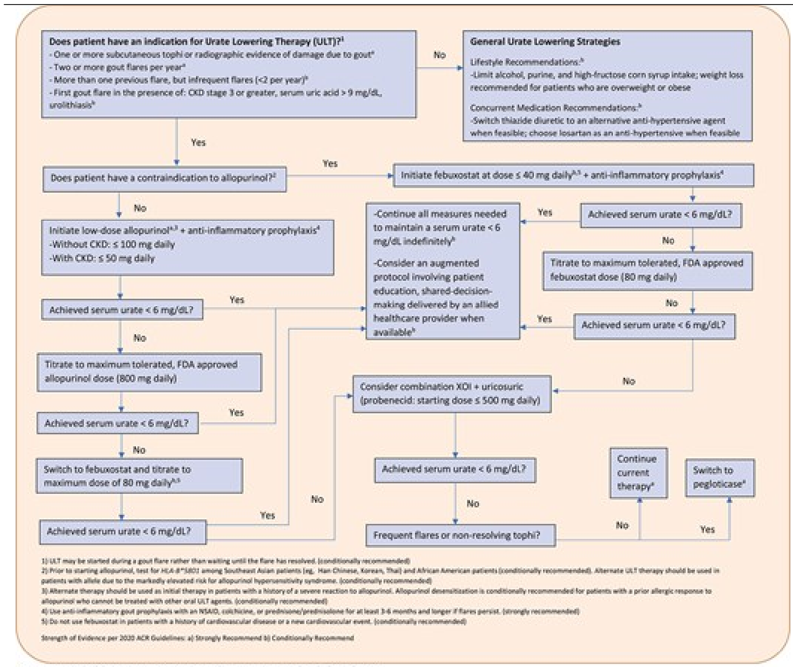
③ The ACR guidelines recognize the occurrence of frequent gout flares (two or more attacks per year) as an indication for pharmacologic ULT. Other indications include the presence of one or more tophus and radiographic evidence of damage attributable to gout. A conditional recommendation for ULT initiation exists for patients who have experienced more than one gout attack, but who have infrequent flares (fewer than two per year), as well as for patients experiencing their first flare who have CKD (stage 3 or greater), serum uric acid level greater than 9 mg/dL (535 μmol/L), or urolithiasis.[24] ACR guidelines conditionally recommend that pharmacologic ULT can be safely started during an acute gout attack, citing evidence that initiation of ULT during an acute attack did not prolong duration or worsen severity of the attack compared to delayed initiation.[24,48-50]

Reduction in serum urate concentrations can be accomplished pharmacologically by decreasing the synthesis of uric acid (xanthine oxidase inhibitors) or by increasing the renal excretion of uric acid (uricosurics).

The ACR guidelines provide a step-wise approach to the treatment of hyperuricemia in patients with gout (Fig. 113-6).[24]

FIGURE 113-6

Algorithm for management of hyperuricemia. (CKD, chronic kidney disease; XOI, xanthine-oxidase inhibitor.) Serum urate levels expressed as 6 mg/dL is equivalent to 357 μmol/L. *(Data from FitzGerald JD, Dalbeth N, Mikuls TB, 2020 American College of Rheumatology Guideline for the Management of Gout. Arthritis Care Res. 72:744–760.)*



Does patient have an indication for Urate Lowering Therapy (ULT)?^{1}
- One or more subcutaneous tophi or radiographic evidence of damage due to gout^{a}
- Two or more gout flares per year^{a}
- More than one previous flare, but infrequent flares (<2 per year)^{b}
- First gout flare in the presence of: CKD stage 3 or greater, serum uric acid > 9 mg/dL, urolithiasis^{b}
No
General Urate Lowering Strategies
Lifestyle Recommendations:^{b}
-Limit alcohol, purine, and high-fructose corn syrup intake; weight loss recommended for patients who are overweight or obese
Concurrent Medication Recommendations:^{b}
-Switch thiazide diuretic to an alternative anti-hypertensive agent when feasible; choose losartan as an anti-hypertensive when feasible
Yes
Does patient have a contraindication to allopurinol?^{2}
Yes
Initiate febuxostat at dose ≤ 40 mg daily^{b,5} + anti-inflammatory prophylaxis^{4}
No
Initiate low-dose allopurinol^{a,3} + anti-inflammatory prophylaxis^{4}
-Without CKD: ≤ 100 mg daily
-With CKD: ≤ 50 mg daily
-Continue all measures needed to maintain a serum urate < 6 mg/dL indefinitely^{b}
-Consider an augmented protocol involving patient education, shared-decision-making delivered by an allied healthcare provider when available^{b}
Yes
Achieved serum urate < 6 mg/dL?
No
Titrate to maximum tolerated, FDA approved febuxostat dose (80 mg daily)
Achieved serum urate < 6 mg/dL?
Yes
No
Yes
Achieved serum urate < 6 mg/dL?
No
Titrate to maximum tolerated, FDA approved allopurinol dose (800 mg daily)
No
Consider combination XOI + uricosuric (probenecid: starting dose ≤ 500 mg daily)
Achieved serum urate < 6 mg/dL?
Yes
No
Switch to febuxostat and titrate to maximum dose of 80 mg daily^{b,5}
Achieved serum urate < 6 mg/dL?
No
Continue current therapy^{a}
Switch to pegloticase^{a}
Yes
No
Achieved serum urate < 6 mg/dL?
Frequent flares or non-resolving tophi?
No
Yes
1) ULT may be started during a gout flare rather than waiting until the flare has resolved. (conditionally recommended)
2) Prior to starting allopurinol, test for HLA-B*5801 among Southeast Asian patients (eg, Han Chinese, Korean, Thai) and African American patients (conditionally recommended). Alternate ULT therapy should be used in patients with allele due to the markedly elevated risk for allopurinol hypersensitivity syndrome. (conditionally recommended)
3) Alternate therapy should be used as initial therapy in patients with a history of a severe reaction to allopurinol. Allopurinol desensitization is conditionally recommended for patients with a prior allergic response to allopurinol who cannot be treated with other oral ULT agents. (conditionally recommended)
4) Use anti-inflammatory gout prophylaxis with an NSAID, colchicine, or prednisone/prednisolone for at least 3-6 months and longer if flares persist. (strongly recommended)
5) Do not use febuxostat in patients with a history of cardiovascular disease or a new cardiovascular event. (conditionally recommended)
Strength of Evidence per 2020 ACR Guidelines: a) Strongly Recommend b) Conditionally Recommend

A xanthine oxidase inhibitor, allopurinol, is recommended as first-line therapy, with an alternate xanthine oxidase inhibitor, febuxostat, as second-line therapy for those with a contraindication or intolerance to allopurinol or who do not achieve target serum urate. In refractory cases, combination therapy including a xanthine oxidase inhibitor plus an agent with uricosuric properties may be considered. Finally, in severe cases, in which the patient is not achieving the target serum uric acid level and is continuing to experience frequent gout flares or non-resolving tophi despite preferred treatments, pegloticase is recommended.

4 The target serum uric acid concentration identified by ACR guidelines is less than 6 mg/dL (357 μmol/L).[24]

Given that the factors associated with uric acid elevation are typically persistent throughout life, urate-lowering therapy is usually prescribed for long-term use. Furthermore, long-term ULT administration has been demonstrated to be more effective in controlling gouty attacks compared to intermittent administration.[51] For these reasons, ACR guidelines recommend indefinite ULT in patients in whom therapy is indicated.[24]

Xanthine Oxidase Inhibitors

5 Xanthine oxidase inhibitors reduce uric acid by impairing the ability of xanthine oxidase to convert hypoxanthine to xanthine and xanthine to uric acid (Fig. 113-1). Because they are efficacious for prophylaxis in both underexcreters and overproducers of uric acid, xanthine oxidase inhibitors are the most widely prescribed agents for the long-term prevention of recurrent attacks of gout. There are two commercially available xanthine oxidase inhibitors, allopurinol and febuxostat.

Allopurinol is an effective urate-lowering agent,[52] but not all patients are able to take it due to adverse effects, and long-term adherence with allopurinol is low.[40] Mild adverse effects such as skin rash, leukopenia, GI problems, headache, and urticaria can occur with allopurinol administration. A more severe adverse reaction known as "allopurinol hypersensitivity syndrome," which includes severe rash (toxic epidermal necrolysis, erythema multiforme, or exfoliative dermatitis), hepatitis, interstitial nephritis, and eosinophilia, reportedly occurs in approximately 1:1,000 patients and is associated with a 20% to 25% mortality rate.[22] The annual incidence rate of allopurinol hypersensitivity is up to 4.68 per 1,000 patients. Risk factors associated with the development of allopurinol hypersensitivity include female sex, age above 60 years, initial starting dose of allopurinol exceeding 100 mg/day, kidney disease, cardiovascular disease, and use of allopurinol for treatment of asymptomatic hyperuricemia.[53] Additionally, the presence of the *HLA-B*5801* allele is associated with increased risk for allopurinol hypersensitivity syndrome (see Pharmacotherapy Considerations later in the chapter).

As evidence has linked higher starting doses of allopurinol with an increased incidence of allopurinol hypersensitivity syndrome, conservative initial dosing is important.[54] ACR guidelines recommend that allopurinol be started at a dose no greater than 100 mg daily in patients with normal kidney function and limited to 50 mg daily in patients with chronic kidney disease (stage 3 or worse).[22,24,26] Despite the cautious approach of initiating at lower doses in patients with CKD, titrating allopurinol to the maximum approved dose has been proven to be safe and effective in this population.[24,55,56] Ideally, the dose of allopurinol should be gradually titrated based on serial serum uric acid measurements until the serum urate target is met, up to a maximum dose of 800 mg/day.[24] During titration, patients should be educated about the signs and symptoms of a serious reaction, including pruritus and rash.

Similar to allopurinol, febuxostat lowers serum urate concentrations in a dose-dependent manner.[57] The recommended starting dose is 40 mg daily and this can be titrated to the maximum FDA-approved dose of 80 mg daily. Although febuxostat and allopurinol may have similar efficacy in serum uric acid lowering and reduction in gout flares,[58,59] an increase in all-cause mortality and cardiovascular mortality has been shown with febuxostat compared to allopurinol.[58] These findings are reflected in an FDA black box warning stating that febuxostat should be reserved for patients unable to take allopurinol.[60] Consistent with this warning, the ACR guidelines recommend febuxostat as an alternative urate-lowering therapy in patients unable to tolerate or unresponsive to allopurinol. Additionally, the guidelines suggest switching to an alternative oral urate-lowering medication in patients taking febuxostat who have a history or cardiovascular disease or a new CVD-related event.[24]

Uricosuric Drugs

⑥ Uricosuric drugs increase the renal clearance of uric acid by inhibiting post-secretory renal proximal tubular reabsorption of uric acid. One uricosuric, probenecid, is available for use in the United States. An alternative uricosuric, benzbromarone, is available in Europe but not in the United States. A third uricosuric, lesinurad, is FDA-approved in the United States but is not currently marketed.[10] Uricosurics offer an alternative and complementary mechanism to xanthine oxidase inhibitors to enhance serum uric acid lowering. Although this class of medications can contribute to meaningful urate lowering and is well tolerated overall, uricosuric therapy is associated with less efficacy in patients with impaired kidney function and, therefore, is not generally recommended in patients with moderate-to-severe CKD (stage 3 or greater).[24,61]

Probenecid

Probenecid is given initially at a dose of 250 mg twice daily for 1 to 2 weeks and then 500 mg twice daily for 2 weeks. Thereafter, the daily dose is increased by 500 mg increments every 1 to 2 weeks until satisfactory control is achieved or a maximum dose of 2 g is reached. Uricosuric therapies, through their action to increase the elimination of uric acid (Fig. 113-1), cause marked uricosuria and may cause stone formation. Probenecid, specifically, has been associated with a 9% to 11% risk of urolithiasis.[22] For this reason, patients with a history of urolithiasis should not use uricosuric drugs.[24,61] The maintenance of adequate fluid intake when using uricosuric therapy is important to diminish the possibility of uric acid stone formation.[61]

In addition to urolithiasis, adverse effects associated with uricosuric therapy include GI irritation, rash/hypersensitivity, and precipitation of acute gouty arthritis. A disadvantage of uricosurics is that salicylates may interfere with this mechanism and result in treatment failure; however, low doses (325 mg/day or less) of enteric-coated aspirin may be used cautiously. In addition, probenecid can inhibit the tubular secretion of other organic acids; thus, increased plasma concentrations of penicillins, cephalosporins, sulfonamides, and indomethacin can occur.

Lesinurad

Lesinurad (Zurampic®) is the first FDA-approved selective uric acid reabsorption inhibitor (SURI). It works by inhibiting urate transporter 1 (URAT1), a transporter found in the proximal renal tubule. Inhibition of URAT1 results in uric acid excretion (Fig. 113-1).

Lesinurad is approved as a combination therapy with a xanthine oxidase inhibitor (including allopurinol and febuxostat) for the treatment of hyperuricemia associated with gout in patients who have not achieved target serum uric acid concentrations with xanthine oxidase inhibitor monotherapy. Because lesinurad works by increasing renal uric acid secretion, it has been associated with adverse renal events (serum creatinine elevation and kidney stones), particularly when used as monotherapy.[62,63] For these reasons, lesinurad carries a black box warning which highlights the increased risk of acute kidney injury when used in the absence of xanthine oxidase inhibitor therapy.[63] Lesinurad retains approval in the United

States, but is not currently being marketed.

Pegloticase

Pegloticase (Krystexxa®) is a pegylated recombinant uricase administered intravenously that works to reduce serum uric acid by converting uric acid to allantoin, a water-soluble and easily excreted substance (Fig. 113-1).

Biweekly pegloticase therapy demonstrates efficacy in reducing serum uric acid and resolving tophi in patients with severe gout and hyperuricemia (uric acid more than or equal to 8 mg/dL [476 µmol/L]) who fail or have a contraindication to allopurinol therapy.[64] Severe gout is defined by having at least one of the following criteria: (a) three or more gout flares within the most recent 18 months, (b) one or more tophi, or (c) joint damage due to gout. Although clearly efficacious, pegloticase has several drawbacks that limit widespread use. One is the route of administration. The biweekly IV infusions of pegloticase must be given over no less than 2 hours, a potential inconvenience to many patients. Furthermore, given potential infusion-related allergic reactions, patients must be treated with antihistamines and corticosteroids before therapy. Cost is another major consideration. Pegloticase is estimated to cost several thousand dollars per month, not including administration costs associated with an IV infusion.[65] This represents a significantly greater cost burden compared with other ULT.[65]

The ideal duration of pegloticase therapy is unknown. Other ULTs such as allopurinol or febuxostat are typically used indefinitely in patients with gout and hyperuricemia. Immunogenicity issues associated with pegloticase therapy may limit the duration with which it may be used effectively. Patients may develop pegloticase antibodies that result in a loss of efficacy after several months.[64]

⑦ Given these many limitations and the narrow patient population in which the drug has been studied, ACR guidelines recommend reserving use of pegloticase for patients with refractory gout for whom all other urate-lowering therapies have failed to reach target serum uric acid and who continue to have frequent gout flares (two or more per year), or who have non-resolving tophi.

Miscellaneous Urate-Lowering Agents

Fenofibrate has been demonstrated to reduce uric acid levels as an ancillary benefit by increasing the clearance of hypoxanthine and xanthine, leading to a sustained reduction in serum urate concentrations. Reductions of 20% to 30% in urate concentrations have been observed with fenofibrate use.[66,67] Despite demonstrated urate-lowering effects, ACR guidelines recommend against adding or switching cholesterol-lowering agents to fenofibrate,[24] as fenofibrate is not considered a preferred therapy in current lipid guidelines.

Losartan, an angiotensin II receptor antagonist, has also demonstrated benefit in reducing serum urate concentrations independent of its primary mechanism, angiotensin receptor antagonism.[68,69] Losartan inhibits renal tubular reabsorption of uric acid and increases urinary excretion, and this effect seems to be a unique property of losartan that is not shared with other angiotensin II receptor antagonists.[70] In addition, it alkalinizes the urine, which helps reduce the risk for stone formation. The ACR guidelines recommend choosing losartan preferentially as antihypertensive therapy in patients with gout when feasible.[24]

Anti-Inflammatory Gout Prophylaxis During Initiation of Pharmacologic Urate-Lowering Therapy

⑧ Initiation of ULT can prompt an acute attack of gout due to remodeling of urate crystal deposits in joints as a result of rapid lowering of urate concentrations.[23] The frequency of this phenomenon ranges from as few as 25% up to 75% of patients.[71] Given this possibility, prophylactic anti-inflammatory pharmacotherapy is recommended to prevent gout attacks and, secondarily, to assist in ensuring patient acceptance of, and adherence with, ULT. The ACR guidelines strongly recommend anti-prophylaxis with NSAIDs, colchicine or prednisone/prednisolone during the first 3 to 6 months of ULT initiation, and longer as needed if gout flares persist.[24] Examples of prophylactic doses for each medication include: colchicine 0.6 mg twice daily, naproxen 250 mg twice/day, and prednisone 10 mg daily (Table 113-6).

Given the considerable duration of therapy required for anti-inflammatory prophylaxis during initiation of ULT, the potential for adverse effects must be considered. Although the risk for gastric ulceration and bleeding is relatively small with short-term NSAID therapy normally employed when treating acute gout flares, administration of a proton-pump inhibitor or other acid-suppressing therapy should be considered to protect from NSAID-induced gastric problems for patients on long-term prophylactic therapy.[23] Prolonged corticosteroid therapy may be linked to many adverse effects not experienced with short-term therapy used for acute treatment (ie, hyperglycemia, Cushing syndrome, fluid retention, hypertension, osteoporosis, glaucoma, depression/euphoria). Therefore, when used for longer-term anti-inflammatory prophylaxis, these risk must be considered.

Cost is another major consideration when selecting prophylactic pharmacotherapy given the need for an extended duration of therapy (3 to 6 months of therapy compared to approximately 1 week for acute gout treatment). Although generic colchicine again became commercially available in 2015, the lack of competition among manufacturers of generic colchicine may allow the cost per tablet to remain high well into the future.[37,72] The cost of colchicine, if not covered by insurance, remains a potential challenge to therapy for certain patients making NSAIDs and corticosteroids more affordable options for patients.

Investigational Drugs

Prior to the approvals of febuxostat in 2009 and pegloticase in 2010, several decades passed without the release of any new pharmacotherapeutic agents for the treatment of gout. Given the increased prevalence of gout and the presence of both treatment intolerance and treatment refractory cases, discovery of novel therapies continues to be a focus of ongoing research.[73]

Interleukin-1 Inhibitors

During acute gout attacks, urate crystals elicit an inflammatory response that triggers the production of interleukin-1 (IL-1).[10] This finding has led to the investigational use of IL-1 inhibitors in the treatment and prevention of acute gout.

Two IL-1 inhibitors, anakinra and canakinumab, have demonstrated efficacy in the treatment of acute gout.[74-76] Neither is approved for the treatment of acute gout by the FDA, and their use remains off-label. As such, the ACR guidelines suggest that use of IL-1 inhibitors should be reserved for treatment for patients experiencing an acute gout attack for whom first-line treatments are ineffective, poorly tolerated, or contraindicated.[24]

Limited evidence also suggests efficacy of IL-1 inhibitors in the prevention of acute gout during the first 16 weeks of ULT initiation (subcutaneous rilonacept 320-mg loading dose followed by 160 mg weekly and subcutaneous canakinumab single dose [50-300 mg] or four times weekly dosing [50 mg—50 mg—25 mg—25 mg]).[76-78] Given the limited evidence and lack of FDA approval for this indication, the ACR guidelines do not provide a recommendation for the use of IL-1 inhibitors for anti-inflammatory prophylaxis during initiation of ULT.

Other Investigational Agents

Several investigational agents intended to be used for the management of gout are at various stages of development. Uricosurics in development include verinurad and arhalofenate.[73] Arhalofenate also suppresses the production of IL-1β which may potentially lead to a reduction in gout flares, in addition to urate lowering.[79] Other novel mechanisms of action include purine nucleoside phosphorylase (PNP) inhibition (ulodesine) and glucose transporter 9 (GLUT9) inhibition (tranilast).[76,78] Other agents include a xanthine oxidase inhibitor, topioxostat, and a uricase, pergsiticase. Continued research will ultimately define the role of these agents in the management of gout and hyperuricemia.

Nephrolithiasis

⑨ The medical management of uric acid nephrolithiasis includes hydration sufficient to maintain a urine volume of at least 2 to 3 L/day, alkalinization of urine, avoidance of purine-rich foods, moderation of protein intake, and reduction of urinary uric acid excretion.

Maintenance of a 24-hour urine volume of at least 2 L with an adequate intake of fluids is desirable for all patients with gout, but especially for those who form stones. Alkalinizing agents should be used with the objective of making the urine less acidic. Urine pH should be maintained at 6 to 6.5.[80] In this pH range, up to 85% of uric acid will be in the form of the soluble urate ion.

Reduction of urine acidity is usually accomplished by the administration of potassium bicarbonate or potassium citrate 30 to 80 mEq/day (mmol/day).[80] Administration of alkali via sodium salts is a less desirable option for two reasons. First, the sodium-induced volume expansion will increase sodium excretion and can secondarily cause hypercalcemia because calcium passively follows the reabsorption of sodium in the proximal tubule and loop of Henle. In the presence of uric acid, the resultant hypercalcemia can lead to calcium oxalate stone formation. Second, older patients with uric acid kidney stones may also have hypertension, heart failure, or impaired kidney function. Because of these conditions, they should not be overloaded with alkalinizing sodium salts or unlimited fluid intake, as these can worsen these conditions.[80]

Carbonic anhydrase inhibitors (eg, acetazolamide and topiramate) produce rapid and effective urinary alkalinization; however, they are not recommended because they cause metabolic acidosis and hypocitraturia which may result in increased urinary saturation of calcium salts and calcium stone formation.[80]

The mainstay of drug therapy for recurrent uric acid nephrolithiasis is xanthine oxidase inhibitors. They are effective in reducing both serum and urinary uric acid concentrations, thus preventing the formation of calculi.

Uric Acid Lowering in the Absence of Gout

Asymptomatic Hyperuricemia

Questions are often raised regarding the use of drug therapy to treat hyperuricemia in patients who have never experienced a gout attack (ie, asymptomatic hyperuricemia). The purported benefits include prevention of acute gouty arthritis, tophi formation, nephrolithiasis, and chronic urate nephropathy. Furthermore, gout is associated with many comorbidities (eg, CKD, hypertension, obesity, heart failure, diabetes, myocardial infarction, stroke) and increasing levels of hyperuricemia have been associated with increased prevalence of these comorbidities.[81] Drug treatment of asymptomatic hyperuricemia to mitigate development of these conditions is not recommended, as it has not been demonstrated that uric acid lowering therapy prevents disease in such individuals.[10,82,83] Nevertheless, an incidental finding of hyperuricemia should prompt further evaluation of other cardiovascular risk factors.

Pharmacotherapy Considerations

While the ACR guidelines provide clear recommendations regarding use of pharmacotherapy in the management of gout and hyperuricemia, application of these recommendations requires personalization to fit the needs of a specific patient. When making therapeutic choices for an individual, it is critical to evaluate the adverse effect profile of a particular pharmacotherapeutic agent while considering a patient’s baseline risk for those unwanted effects. This involves an analysis of patient demographics and comorbidities.

Allopurinol hypersensitivity syndrome is perhaps the most concerning adverse effect of all potential side effects associated with gout therapies, given the high mortality rate associated with this reaction. As such, it would be ideal if patients at high risk for developing this syndrome could be screened for and, consequently, guided to alternative therapy. The *HLA-B*5801* allele has been associated with a significant increase risk for allopurinol hypersensitivity syndrome. Patients of Korean, Han Chinese, Thai, and African descent have been identified as having a high prevalence of this allele and, therefore, at increased risk for allopurinol hypersensitivity syndrome. For this reason, the ACR guidelines recommend that *HLA-B*5801* testing be pursued before allopurinol initiation in these specific populations.[24] For those found to be positive, alternative therapy should be used.[84]

Certain comorbidities may warrant dose adjustment of some gout therapies or, in certain instances, complete avoidance of certain medications. For example, patients with impaired kidney function should generally avoid NSAID therapy and should receive colchicine at reduced doses. Patients with GI disease should also avoid NSAID therapy and may not be able to tolerate colchicine therapy; in these patients, corticosteroid therapy may be a better option. Patients with uncontrolled diabetes may experience hyperglycemia with use of corticosteroids and, therefore, should avoid these agents and preferably use NSAIDs or colchicine instead. In addition to comorbidities, polypharmacy and cost considerations may affect treatment decisions in an individual patient. The comprehensive management of gout provides ample opportunity for pharmacists to apply medication expertise, and care models incorporating pharmacists in the management of gout have demonstrated improved outcomes compared to standard practice.[85] Refer to Table 113-9 for an overview of important factors to consider when personalizing pharmacotherapy for an individual patient with gout.

TABLE 113-9

Pharmacotherapy Considerations in Gout

Conditions and	Limitations to Pharmacotherapy	Alternative Therapies

Situations		
Impaired Kidney Function	NSAIDs may lead to exacerbation of kidney impairment	Consider reduced-dose colchicine or corticosteroids for short-term treatment of acute gout Consider reduced-dose colchicine for prophylaxis during initiation of urate-lowering therapy
	Uricosuric therapy is ineffective in patients with impaired kidney function	Consider allopurinol or febuxostat
	Lesiurad is not indicated in patients with impaired kidney function	Consider allopurinol or febuxostat for first-line urate-lowering therapy; consider pegloticase for refractory cases
GI disease	Colchicine may cause GI upset and diarrhea	Consider corticosteroids for treatment of acute gout If monoarticular, consider joint injection
	NSAIDs may cause GI bleeding or ulceration	Consider gastroprotection with coadministration of proton-pump inhibitor when NSAID therapy is used Consider colchicine or corticosteroids for treatment of acute gout Consider low-dose colchicine for prophylaxis during initiation of urate-lowering therapy
Congestive heart failure	NSAIDs may cause a congestive heart failure exacerbation	Consider colchicine for treatment of acute gout Consider colchicine for prophylaxis during initiation of urate-lowering therapy
	Concurrent use of diuretic may increase serum urate	If diuretic remains necessary, consider initiating urate-lowering therapy Consider losartan as a therapy for congestive heart failure given its uricosuric properties
Hypertension	Diuretics may increase uric acid	Consider losartan as alternative or additional antihypertensive therapy given its uricosuric properties Consider non-diuretic anti-hypertensive agents as alternative therapy Consider addition of urate-lowering therapy if diuretic remains necessary
	NSAIDs may worsen blood pressure control	Consider colchicine or corticosteroids for treatment of acute gout Consider colchicine for prophylaxis during initiation of urate-lowering therapy
Polypharmacy	CYP3A4 inhibitors and P-glycoprotein inhibitors interact with colchicine leading to elevated colchicine levels	Reduce the dose of colchicine used for the treatment and prophylaxis of acute gout

		Consider NSAIDs or corticosteroids for treatment of acute gout Consider NSAIDs for prophylaxis during initiation of urate-lowering therapy
	Added pharmacotherapy may be undesirable in a patient with a large medication burden	Consider losartan as urate-lowering therapy in patients with comorbid hypertension Consider fenofibrate as urate-lowering therapy in patients with hypertriglyceridemia
Financial limitations	Febuxostat and colchicine are considerably more costly compared with other gout treatments	Consider allopurinol as urate-lowering therapy Consider NSAIDs or corticosteroids for treatment of acute gout Consider NSAIDs for prophylaxis of gout during initiation of urate-lowering therapy

CYP, cytochrome P450; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug.

Evaluation of Therapeutic Outcomes

Follow-up of patients with gout depends on the frequency of attacks and on the medications used to treat symptoms. For a patient who is experiencing a first attack of gout, long-term therapy is generally not indicated; however, patients having a first attack should be educated about the likelihood of recurrence and what to do if another attack occurs. Approximately 60% of patients have a second attack within the first year, and 78% have a second attack within 2 years. Only 7% of patients do not have a recurrence within a 10-year period.[39]

Baseline blood work for patients receiving ULT chronically should include kidney function (serum creatinine), liver enzymes (aspartate aminotransferase, alanine aminotransferase), complete blood count, and electrolytes. There is generally no need to recheck these laboratory parameters for patients undergoing acute therapy with an NSAID or colchicine of limited duration. However, for patients requiring long-term therapy or prophylaxis, they should be rechecked every 6 to 12 months or as clinically indicated. For patients suspected of having an acute attack of gouty arthritis, it is reasonable to check a serum uric acid concentration, particularly if it is not the first attack and a decision is to be made regarding initiation of prophylactic therapy. However, clinicians should be mindful that acute gouty arthritis can occur in the presence of normal serum uric acid concentrations.[1] During titration of ULT, serial uric acid measurements should be obtained; once the urate target is achieved, uric acid should be monitored periodically (every 6-12 months).[10] This monitoring regimen is recommended not only to insure appropriate dosing of ULT, but also to serve as an assessment of patient adherence given the known adherence issues with ULTs. ⑩ Because of the high rates of comorbidities associated with gout, including diabetes mellitus, CKD, hypertension, obesity, coronary heart disease, heart failure, and stroke, an elevated uric acid concentration or an acute attack of gout should prompt evaluation for these related comorbidities and implementation of appropriate risk reduction measures.[81] Additionally, clinicians should look for possible underlying causes of hyperuricemia that may be actionable, such as medications (eg, diuretics, niacin, calcineurin inhibitors), obesity, malignancy, and alcohol abuse. Nonpharmacologic options include encouraging patients to exercise, lose weight, and reduce their consumption of alcohol and syrup-sweetened sodas. Periodic follow-up is necessary to address progress on these goals.

CONCLUSION

Hyperuricemia can be asymptomatic without complications, or it may lead to acute attacks of gouty arthritis, chronic gout, and uric acid nephrolithiasis. Treatment of asymptomatic hyperuricemia is not recommended, although lifestyle modifications (eg, weight loss, reduction of alcohol intake, control of blood pressure) should be encouraged to help reduce serum urate and improve overall health.

Acute gouty arthritis responds well to short courses of NSAIDs, colchicine, or corticosteroids to treat the underlying inflammatory response. The management of uric acid nephrolithiasis includes hydration and alkalinization of the urine. Prevention of recurrent gouty arthritis or recurrent nephrolithiasis, as well as the treatment of chronic gout, requires hypouricemic therapy with either a xanthine oxidase inhibitor, uricosuric, or a combination of both therapies. Allopurinol is the ULT with the strongest safety and efficacy profile, making it the first-line choice for prevention of gout attacks in patients needing prophylactic therapy who do not have contraindications. Finally, anti-inflammatory prophylaxis with colchicine, NSAID, or an oral corticosteroid is indicated during the initiation of ULT to prevent the development of acute gout due to the rapid mobilization or urate.

ABBREVIATIONS

ACR	American College of Rheumatology

SELF-ASSESSMENT QUESTIONS

1. Which course of action is recommended in patients with asymptomatic hyperuricemia?

A. Initiate treatment with urate-lowering therapy such as allopurinol or feboxustat

B. Initiate treatment with a nonsteroidal anti-inflammatory drug

C. Initiate treatment with colchicine

D. Recommend lifestyle measures to reduce serum urate level

2. Which of the following individuals would have the highest risk of developing gout?

A. An obese, 60-year-old male

B. A pre-menopausal, 40-year-old female

C. A physically active, 30-year-old male

D. A 45-year-old female with serum uric acid <7 mg/dL (416 µmol/L)

3. Which of the following is the most likely site for an acute attack of monoarticular gouty arthritis?

A. First metatarsophalangeal joint

B. Ankle

C. Heel

D. Knee

4. The American College of Rheumatology recommends which approach to lower risk of gout flares in patients who are candidates to receive urate-lowering therapy?

A. Treat-to-target, goal serum urate <7 mg/dL (416 µmol/L)

B. Treat-to-target, goal serum urate <6 mg/dL (357 µmol/L)

C. Fixed dose, allopurinol 300 mg/day

D. Fixed dose, febuxostat 40 mg/day

5. Which of the following is a first-line therapy to treat an acute gout flare?

A. Adrenocortocotropic hormone

B. Prednisone

C. Allopurinol

D. High-dose colchicine

6. Which of the following agents is a preferred first-line urate-lowering therapy in patient with moderate-to-severe CKD?

A. Febuxostat

B. Pegloticase

C. Allopurinol

D. Probenecid

7. How long should prophylaxis for acute gout flare be given after initiation of urate-lowering therapy?

    A. 1-2 weeks

    B. 2-4 weeks

    C. 1-3 months

    D. 3-6 months

8. Which of the following is the most appropriate initial dosing strategy for colchicine used to treat an acute gout flare in patient with normal renal function?

    A. 0.6 mg one dose

    B. 0.6 mg hourly until symptoms subside

    C. 1.2 mg initially, followed by 0.6 mg one hour later

    D. 1.2 mg hourly until symptoms subside

9. In which of the following patient scenarios should urate-lowering therapy be initiated?

    A. After resolution of an initial gout flare in a 65-year-old male with no prior history of acute gout

    B. An 80-year-old female found incidentally to have hyperuricemia on labs conducted as part of her annual wellness physical.

    C. During an initial gout flare in a 75-year-old male found to have a serum urate of 10 mg/dL (595 μmol/L).

    D. After resolution of a gout flare in a 60-year-old female whose only other attack of gout was 5 years ago after initiating hydrochlorothiazide.

10. What is the best option for treatment of acute gouty arthritis of the great toe in a 65-year-old female with a past medical history significant for atrial fibrillation and who takes apixaban?

    A. Low-dose colchicine

    B. Febuxostat

    C. Intra-articular corticosteroid injection

    D. Indomethacin

11. Which of the following lifestyle modifications should be recommended in patients with gout, regardless of disease activity?

    A. Increasing dietary purine intake

    B. Adding vitamin C supplements

    C. Limiting alcohol intake

    D. Increasing consumption of high-fructose corn syrup products

12. Which of the following would be the most appropriate initial treatment option for a patient with uncontrolled diabetes, and no other past medical history, experiencing a polyarticular attack of acute gout?

    A. Prednisone 40 mg daily for 5 days, then taper by 10 mg every 3 days until off

B. Naproxen 250 mg TID until resolved

C. Colchicine 1.2 mg initially, then 0.6 mg hourly until symptoms have resolved or diarrhea occurs

D. Triamcinolone 40 mg × 1 dose intra-articularly

13. Which of the following is the best option for a patient with gout taking allopurinol 300 mg daily with a serum uric acid level of 7.4 mg/dL (440 µmol/L)?

A. Add febuxostat 40 mg daily

B. Add probenecid 500 mg daily

C. Add fenofibrate 145 mg daily

D. Increase the allopurinol dose to 400 mg daily

14. Which of the following is the best option for a patient of Southeast-Asian descent who carries the *HLA-B*58:01* variant and who presents with a history of three gout attacks in the past year and a current serum uric acid level of 8.4 mg/dL (500 µmol/L). The patient has no other significant PMH.

A. Initiate allopurinol 50 mg daily plus colchicine 0.6 mg daily

B. Initiate febuxostat 40 mg daily plus colchicine 0.6 mg daily

C. Initiate pegloticase 8 mg IV every two weeks daily plus colchicine 0.6 mg daily

D. Urate-lowering therapy not indicated

15. Which of the following should be recommended for a patient with monoarticular acute gouty arthritis unable to take oral medications?

A. Pegloticase

B. Topical naproxen

C. Methylprednisolone 40 mg IM

D. Heating pad

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** For patients with asymptomatic hyperuricemia, the American College of Rheumatology recommends against initiating urate-lowering therapy in patients with asymptomatic hyperuricemia, since the benefits would not outweigh potential treatment costs or risks for most patients. Lifestyle measures designed to reduce serum urate concentrations should be recommended.

2. **A.** Obese persons are twice as likely as non-obese persons to have gout. Gout is rare in individuals with serum uric acid <7 mg/dL (416 µmol/L), and in younger adults (particularly pre-menopausal females).

3. **A.** The first metatarsophalangeal joint (great toe) is most often affected in an attack of acute gout, and then in order of frequency, the insteps, ankles, heels, knees, wrists, fingers, and elbows.

4. **B.** The American College of Rheumatology recommends a treat-to-target management strategy to achieve a serum urate target of <6 mg/dL (357 µmol/L) in patients receiving urate-lowering therapy, over a fixed-dose strategy.

5. **B.** Based on similar efficacy between agents, NSAIDs, glucocorticosteroids, or low-dose colchicine are all recommended as first-line therapy to treat an acute gout flare.

6. **C.** Allopurinol is the preferred first-line agent recommended by the American College of Rheumatology for urate-lowering therapy due to tolerability, safety, and lower cost, including patients with CKD. Lower starting doses help mitigate safety issues.

7. **D.** Anti-inflammatory prophylaxis should be given when initiating urate-lowering therapy, and it should be continued for at least 3 to 6 months after urate-lowering therapy is initiated. Shorter durations have been associated with flares upon cessation of prophylaxis.

8. **C.** Data submitted in support of the FDA approval of Colcrys showed that a lower dose of colchicine (1.2 mg initially, followed by a single 0.6-mg dose one hour later) was as effective as traditionally used higher doses, but better tolerated.

9. **C.** The American College of Rheumatology recommends starting urate-lowering therapy during an acute gout flare rather than risking the patient not returning for urate-lowering therapy initiation. Additionally, patients may be highly motivated to initiate therapy due to the symptoms related to their current flare. While it is traditionally recommended against starting urate-lowering therapy in patients who have their first gout flare, the American College of Rheumatology recommends it be considered in certain patients, including those with comorbid CKD (stage ≥3), serum urate concentration >9 mg/dL (535 μmol/L), or urolithiasis.

10. **A.** Colchicine, NSAIDs, or glucocorticoids are all appropriate first-line therapy for gout flare, with the choice of which agent determined by patient specific factors. In this scenario, the presence of apixaban and increased bleeding risk makes indomethacin less viable. Although intra-articular corticosteroid injection could be used, the difficulty in injecting the great toe makes this a less attractive option. Low-dose colchicine is the most appropriate agent in this case given lack of interaction with apixaban and likelihood of early resolution of symptoms with minimal exposure to the medication.

11. **C.** Lifestyle modifications are important to minimize the risk of gout flares. These include limiting alcohol intake, eating a diet low in purines and high-fructose corn syrup products, and losing weight. Vitamin C supplementation has limited evidence of effects on serum urate.

12. **B.** Prednisone would not be a good choice because it may worsen the already uncontrolled diabetes. Colchicine could be used, but the dosing listed is inappropriate. Because it is polyarticular, steroid injection is not feasible. Naproxen would be the best choice in this case.

13. **D.** The maximum dose of allopurinol is 800 mg daily. The dose should be optimized prior to considering dual therapy with a uricosuric therapy making choice D correct and choice B incorrect. Choice A is incorrect because febuxostat would be considered duplicate therapy when combined with allopurinol given that they are both xanthine oxidase inhibitors (XOIs). Fenofibrate does have urate-lowering properties; however, the effect is not as substantial as the effects of XOIs or uricosurics so it is not recommended as a standalone urate-lowering therapy. Furthermore, fibrates are not generally preferred for the management of lipid disorders according to most current lipid guidelines so fenofibrate is rarely indicated.

14. **B.** Allopurinol should be avoided in patients with the *HLA-B*58:01* variant due to increased risk of allopurinol hypersensitivity syndrome in these patients. Febuxostat is the preferred agent in these instances, especially if the patient is free from cardiovascular disease (the most serious concern limiting widespread febuxostat use). Pegloticase is reserved for patients with refractory disease due to high cost and limited information on successful long-term therapy. Choice D is incorrect because the patient has frequent gout attacks (> 2 per year) combined with elevated uric acid and, therefore, is a candidate for ULT.

15. **C.** For patients experiencing an acute attack of gout who cannot take oral medications, treatment with glucocorticoids (intramuscular, intravenous, or intra-articular) are recommended. Local ice therapy, not a heating pad, can be used as an adjuvant. Pegloticase is used to lower serum urate and would not be effective in relieving the pain from an acute gout attack.

Chapter 114: Glaucoma

Richard G. Fiscella; Ohoud A. Owaidhah; Deepak P. Edward

KEY CONCEPTS

KEY CONCEPTS

① Primary open-angle glaucoma (POAG) or ocular hypertension is more prevalent outside Asia than primary angle-closure glaucoma (PACG).

② In any form of glaucoma, reduction of intraocular pressure (IOP) is essential.

③ IOP is an important risk factor for glaucoma, but the most important considerations are progression of glaucomatous changes in the back of the eye (optic disk and nerve fiber layer) and visual field changes when diagnosing and monitoring for POAG or ocular hypertension.

④ Optic nerve changes often occur before visual field changes are exhibited.

⑤ Reduction in IOP prevents progression or even onset of glaucoma.

⑥ Newer medications simplify treatment regimens for patients. Prostaglandin analogs are considered the most potent topical medications for reducing IOP and flattening diurnal variations in IOP.

⑦ Local adverse events are common with topical glaucoma medications, but patient education and reinforcing adherence are essential to prevent glaucoma progression.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video from Dr. Henry Jampel, a leading glaucoma specialist, entitled “Using Eye Drops to Treat Glaucoma” from The Wilmer Eye Institute (https://www.youtube.com/watch?v=IR7nH1kXsBY). Proper administration of eye drops is critical prior to discussing glaucoma medication with a patient. The video presents common mistakes associated with eye drop administration, the proper technique for administering eye drops, and frequently asked questions about using eye drops in glaucoma. It is a useful tool for the students to help ensure that the proper use of eye drops in glaucoma in the ASSESS and IMPLEMENT steps for the Patient Care Process.

INTRODUCTION

Glaucomas are a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Increased intraocular pressure (IOP) is thought to play an important role in the pathogenesis of glaucoma, but it is not a diagnostic criterion for glaucoma. Consistently elevated IOP without signs or symptoms of glaucoma is called ocular hypertension (OHT).

Two major types of glaucoma have been identified: open angle and closed angle. Primary open-angle glaucoma (POAG) accounts for the great majority of cases in North America, while primary angle-closure glaucoma (PACG) is more prevalent in Asia. Either type can be a primary inherited disorder, congenital, or secondary to disease, trauma, or drugs and can lead to serious complications. Both primary and secondary glaucomas may be caused by a combination of open-angle and closed-angle mechanisms (Table 114-1 and Fig. 114-1). Patients with consistently high IOP or patients with clinical findings suspicious of early glaucomatous changes are called "glaucoma suspects."[1,2]

FIGURE 114-1

Aqueous humor drainage pathways in normal eyes and eyes with glaucoma. The cross-section demonstrates aqueous humor drainage in the normal healthy eye, and in primary open-angle glaucoma (POAG) and primary angle closure glaucoma (PACG). The three diagrams indicate the following aqueous humor pathways: (*A*) healthy eye, (*B*) POAG, and (*C*) PACG. Aqueous humor exits the anterior chamber by two routes: The trabecular meshwork (conventional) with approximately 80%-85% of outflow through to Schlemm's canal and the rest of the aqueous humor filtering through the uveoscleral (unconventional) outflow pathway (ciliary body and the suprachoroidal space). POAG is often associated with increased resistance to aqueous humor drainage at the trabecular meshwork. In PACG the drainage pathway is often obstructed by the iris. *(Figure by Lauren Kalinoski, MS, CMI. Courtesy University of Illinois at Chicago Department of Ophthalmology, Chicago, Illinois)*.

BASIC CONCEPTS

Aqueous Humor Dynamics and IOP

An understanding of IOP and aqueous humor dynamics will assist the reader in understanding the drug therapy of glaucoma.[1-6]

Aqueous humor is a clear fluid and ultrafiltrate of the serum that fills and helps to form the anterior and posterior chambers of the eye.[7] It is formed in the ciliary body and its epithelium through both filtration and secretion. Because ultrafiltration depends on pressure gradients, blood pressure and IOP changes influence aqueous humor formation. Osmotic gradients produced by active secretion of sodium and bicarbonate and possibly by other solutes such as ascorbate from the ciliary body epithelial cells into the aqueous humor result in the movement of water from the pool of ciliary stromal ultrafiltrate into the posterior chamber, forming aqueous humor. Carbonic anhydrase (primarily isoenzyme type II), α- and β-adrenergic receptors, and sodium- and potassium-activated adenosine triphosphatases are found on the ciliary epithelium and appear to be involved in this secretion of the solutes sodium and bicarbonate.

Receptor systems controlling aqueous inflow have not been elucidated fully. Pharmacologic studies suggest that β-adrenergic agents increase inflow, whereas α_2-adrenergic blocking, β-adrenergic blocking dopamine-blocking, carbonic anhydrase-inhibiting, melatonin-1 agonist, and adenylate cyclase-stimulating agents decrease aqueous inflow. Aqueous humor produced by the ciliary body is secreted into the posterior chamber at a rate of approximately 2 to 3 μL/min. The pressure in the posterior chamber produced by the constant inflow pushes the aqueous humor between the iris and lens and through the pupil into the anterior chamber of the eye (see Fig. 114-1).[1-6]

Aqueous humor in the anterior chamber leaves the eye by two routes: (a) filtration through the trabecular meshwork (conventional outflow) to the Schlemm's canal (80%-85%) and (b) through the ciliary body and the suprachoroidal space (uveoscleral outflow or unconventional outflow) (see Fig. 114-1). Cholinergic agents such as pilocarpine appear to increase outflow by physically opening the meshwork pores secondary to ciliary muscle contraction. The nitric oxide group on latanoprost bunod is believed to cause trabecular relaxation and increased trabecular meshwork outflow. ROCK inhibitors are believed to increase aqueous humor outflow through the trabecular meshwork. Prostaglandins are thought to result in remodeling of extracellular matrix in the meshwork, thereby increasing mainly uveoscleral outflow. The uveoscleral outflow of aqueous humor is increased by prostaglandin analogs, and α_2-adrenergic agonists. Constant inflow of aqueous humor from the ciliary body and resistance to outflow result in an IOP great enough to produce an outflow rate equal to the inflow rate (see Fig. 114-1). Novel adenosine receptor agonists, cannabinoids, serotonin agents, and dopamine agonists also increase aqueous humor outflow and reduce IOP.[1-4,6]

The median IOP measured in large populations is 15.5 ± 2.5 mm Hg (2.1 ± 0.3 kPa); however, the distribution of pressures around the mean is skewed to the right (toward higher readings). IOP is not constant and changes with pulse, blood pressure, forced expiration or coughing, neck compression, and posture. Gender, general health, and lifestyle (eg, smoking) are some factors that may have a long-term effect on the IOP.[5,7-11] The amount of caffeine in one cup of caffeinated coffee (182 mg) increases IOP by about 1 mm Hg (0.1 kPa) after 90 minutes; this increase in IOP is not clinically relevant. Patients who have thinner corneas, have had laser refractive eye surgery (LASIK), or have had cataract surgery demonstrate falsely low IOP readings. IOP is measured by tonometry: indentation tonometry, applanation tonometry, or a noncontact method using an air pulse. Newer methods of tonometry include the Pascal tonometer, Icare™ rebound tonometer, and a contact lens-based investigational device that can remotely monitor 24-hour IOP changes from baseline.[7] These methods may result in slightly different pressure readings. IOPs consistently greater than 21 mm Hg (2.8 kPa) are found in 5% to 8% of the general population. The incidence increases with age, such that "abnormal" (ie, >22 mm Hg [2.9 kPa]) IOP is found in 15% of those 70 to 75 years of age. Intermittently very high IOP (>40 mm Hg [5.3 kPa]) is found in patients with PACG.

IOP demonstrates considerable circadian variation (often referred to as *diurnal* IOP or the IOP during the daily 24-hour cycle) primarily because of changes in the rate of aqueous humor formation. This circadian variation results in a minimum IOP at approximately 6 pm and a maximum IOP at awakening, although some studies suggest that both healthy and glaucoma patients may have their highest IOP at night after falling asleep.[1-6,8-14] Low systemic blood pressure in conjunction with high IOPs (decreased ocular perfusion pressure) at night can result in optic nerve head damage. Generally, the circadian IOP variation is less than 3 to 4 mm Hg (0.4-0.5 kPa); however, it may be greater for patients with glaucoma. This circadian variation and the variable relationship of IOP with visual loss make measurement of IOP a poor screening test for glaucoma. Controlling circadian increases in IOP is thought to be important in the prevention of disease progression. Prostaglandin analogs and carbonic anhydrase inhibitors (CAIs) reduce nocturnal IOP, whereas beta blockers and alpha-2 adrenergic agents have minimal effects.[1-6,8-15]

Although increased IOP within any range is associated with a higher risk of glaucomatous damage, it is both an insensitive and nonspecific diagnostic and monitoring tool. Of individuals with IOP between 21 and 30 mm Hg (2.8-4.0 kPa), only 0.5% to 1% per year will develop optic disk changes and visual field loss (ie, glaucoma) over 5 to 15 years. However, more subtle retinal damage, such as alteration of color vision or decreased contrast sensitivity, occurs in a higher percentage of patients with IOPs greater than 21 mm Hg (2.8 kPa), and the incidence of visual field defects increases to as high as 28% in individuals with IOPs above 30 mm Hg (4.0 kPa). For a given IOP finding, the risk of developing glaucoma increases with older age, family history of glaucoma, lower ocular perfusion pressure, lower blood pressure, thinner central cornea, optic disc hemorrhage, larger cup-to-disk ratio, and specific visual fields findings. For patients with preexisting optic nerve damage, the worse the existing damage, the more sensitive the eye is to a given IOP. As many as 20% to 30% of patients with glaucomatous visual field loss have an IOP of less than 21 mm Hg (2.8 kPa) (called *normal-tension glaucoma*, referring to the normal IOP). Thus, the absolute IOP is a less-precise predictor of optic nerve damage. More direct measurements of therapeutic outcome, such as optic disk examination and visual field evaluation, also must be used as monitors of disease progression. Taking the above factors into consideration, glaucoma medications that provide maximal reduction of IOP over 24 hours and have minimal influence on blood pressure may be advantageous in treating glaucoma patients.[1-5,8-17]

Optic Disk and Visual Fields

The optic disk is the portion of the optic nerve ophthalmoscopically visible as it leaves the eye. It consists of approximately 1 million retinal ganglion nerve cell axons, blood vessels, and supporting connective tissue structures (lamina cribrosa). The small depression within the disk is termed the *cup*. A normal physiologic cup does not extend beyond the optic nerve rim and has a varying diameter of less than one-third to one-half that of the disk (cup-to-disk ratio: 0.33-0.5). Table 114-2 lists the common alterations of the optic disk found in glaucoma. These disk changes result from optic nerve axonal degeneration and remodeling of the supporting structures. As the nerve axons die, the cup becomes larger in relation to the whole disk. A loss of retinal nerve fiber layer might be visualized in glaucoma patients with detectable visual field loss (see Fig. 114-2). This pattern of changes is consistent with visual field losses and loss of visual sensitivity seen in glaucoma.[1-6,8-15] Damage to the optic nerve can be documented by optic disk photographs, and disease stability or progression may be monitored by examining sequential photographs. Newer methods of assessing damage to the retinal nerve fiber layer and optic disk have been described. These include scanning laser polarimetry (GDX), confocal laser ophthalmoscopy (Heidelberg retinal tomography, or HRT), and optical coherence tomography (OCT). These methods offer the ability to assess the damage to the optic nerve quantitatively.

TABLE 114-2

Optic Disk and Visual Field Findings in Patients with Glaucoma

Optic disk
Cup-to-disk ratio >0.5
Progressive increase in cup size
Cup-to-disk ratio asymmetry >0.2
Vertical elongation of the cup
Excavation of the cup
Increased exposure of lamina cribrosa
Pallor of the cup
Splinter hemorrhages
Cupping to edge of disk
Notching of the cup (usually superior or inferior)
Nerve fiber defects
Visual field findings
General peripheral field constriction
Isolated scotomas (blind spots)
Nasal visual field depression (“nasal step”)
Enlargement of blind spot
Large arc-like scotomas
Reduced contrast sensitivity
Reduced peripheral acuity
Altered color vision

Determination of the visual field allows the assessment of optic nerve damage and is an important monitoring parameter in the treatment. However, visual field changes typically lag behind optic disk changes, and a loss of 25% to 35% of retinal ganglion cells is usually required before detectable visual field defects are noted. The peripheral visual field is measured using a visual field instrument called a *perimeter*. Characteristic visual field loss occurs in glaucoma (Fig. 114-2; see also Table 114-2), but loss of central visual acuity usually does not occur until late in the disease. Other indicators, such as color vision changes and contrast sensitivity, may allow earlier and more sensitive detection of glaucomatous changes.[1-4]

FIGURE 114-2

Normal, moderate glaucoma, and severe glaucoma disc damage and their corresponding visual fields. (*A*) The photograph shows the normal optic disc, and the corresponding visual field test shows a normal visual field. The physiologic “blind spot” (dark area on the visual field) corresponds to the location of the optic nerve. (*B*) The eye with moderate glaucoma shows an enlarged cup and thinning of the inferior neuro-retinal rim with the arrowhead pointing to the optic disc notch. Note the arrow pointing to the corresponding superior visual field defect. The physiologic “blind spot” corresponds to the location of the optic nerve. (*C*) In severe glaucoma, there is severe loss of the optic disc rim and enlargement of the cup (see arrows). The corresponding visual field shows a significant loss of visual field in both superior and inferior hemifields. *(Courtesy University of Illinois at Chicago Department of Ophthalmology, Chicago, Illinois, and King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia.)*

Genetics

Glaucoma is often inherited as a complex multifactorial disease, but it can also be inherited as a Mendelian autosomal-dominant or autosomal-recessive trait form. The common age-related adult-onset glaucoma, like POAG, although containing heritability of some significance, is more complex and is influenced by environmental factors. Genetic studies have more clearly defined the underlying molecular events responsible for the Mendelian forms of the disease. However, the chromosome locations identified may play some factor in the more complex forms. Several major gene loci associated with POAG have been identified. The molecular mechanism of how mutations in any of these genes result in increased IOP with loss of visual field has not been determined. The future of genetic studies in glaucoma will include the discovery of new glaucoma genes, determination of clinical phenotypes associated with these genes and mutations, understanding how environmental factors interact, and developing a database that can be used for further testing.

Genome-wide association studies have identified new loci that are associated with clinically relevant optic disc parameters, including the optic disc area and vertical cup-to-disc ratio. Genes associated with chronic angle-closure glaucoma have also been identified. Improved understanding of the genetic origins of POAG may lead to new diagnostic tools and therapies that target the underlying causes of the disease.[1-4,14,18]

Epidemiology of Ocular Hypertension, Glaucoma Suspects, and Open-Angle Glaucoma

① Overall, OHT occurs in 4.5% of non-Hispanic Whites in the United States. The frequency increases to 7.7% of those older than 79 years.[19-22] The number of glaucoma suspects (ie, consistently high IOP or suspicious eye findings) is thought to be 3 to 6 million individuals in the United States. Approximately 2% of glaucoma suspects who are left untreated will progress to glaucoma each year.[7]

Open-angle glaucoma (OAG) is the second leading cause of blindness, affecting up to 4 million individuals in the United States and up to 70 million individuals worldwide. More than 135,000 persons in the United States and about 6 to 7 million in the world have glaucoma-related bilateral blindness. The prevalence rate varies with age, race, diagnostic criteria, and other factors. In the United States, OAG occurs in 1.5% of the population older than 30 years, 1.3% of Whites, and 3.5% of Blacks. Data have also suggested that the prevalence of OAG and ocular hypertension is also high among Latinos of Mexican ancestry, with approximately 4.74% and 3.56% of people affected, respectively.[23]

The incidence of OAG increases with increasing age. The incidence of the disease for patients aged 80 years is 3% in Whites and 5% to 8% in Blacks. In addition to increased IOP, age, and ethnicity, the risk of glaucoma increases with family history, thinner central corneal thickness, lower ocular perfusion pressure, Type II diabetes, myopia, and certain genetic mutations.[7,14,18-21]

Etiology of Open-Angle Glaucoma

② The specific cause of glaucomatous optic neuropathy is presently unknown. Previously, increased IOP was considered to be the sole cause of the damage; however, it is now recognized that IOP is only one of the many factors associated with the development and progression of glaucoma. Increased susceptibility of the optic nerve to ischemia (a reduced or dysregulated blood flow), excitotoxicity, autoimmune reactions, and other abnormal physiologic processes are likely additional contributory factors. Damage of the optic nerve ganglion occurs at the point at which ganglion and blood vessels pass through the perforated supportive collagen lamina cribosa of the optic disc. The outcome of these processes is believed to be apoptosis of the retinal ganglion cells, which results in axonal degeneration and finally permanent loss of vision. Neuronal loss also extends beyond the optic nerve to the lateral geniculate nucleus and visual cortex. POAG may represent a number of distinct diseases or conditions that simply manifest the same symptoms. Susceptibility to visual loss at a given IOP varies considerably; some patients do not demonstrate damage at high IOPs, whereas other patients have progressive visual field loss despite an IOP in the normal range (normal-tension glaucoma).[1-5,7]

Although IOP poorly predicts which patients will have visual field loss, the risk of visual field loss clearly increases with increasing IOP within any range. Lowering IOP, no matter what the pretreatment IOP, reduces the risk of glaucomatous progression or may even prevent the onset to early glaucoma in patients with ocular hypertension.[1-4,7,8,10,11]

The mechanism by which a certain level of IOP increases the susceptibility of a given eye to nerve damage remains controversial. Multiple mechanisms are likely to be operative in a spectrum of combinations to produce the death of retinal ganglion cells and their axons in glaucoma. Pressure-sensitive astrocytes and other cells in the optic disk supportive matrix may produce changes and remodeling of the disk, resulting in axonal death. Vasogenic theories suggest that optic nerve damage results from insufficient blood flow to the retina secondary to the increased perfusion pressure required in the eye, dysregulated perfusion, or vessel wall abnormalities and results in degeneration of axonal fibers of the retina. Another theory suggests that the IOP may disrupt axoplasmal flow at the optic disk.[7]

Focus on the mechanisms of the retinal ganglion cell apoptosis and the role of excessive glutamate and nitric oxide found in glaucoma patients has broadened the focus of drug therapy research to include evaluation of agents that act as neuroprotectants. Such agents may be particularly useful for patients with normal-pressure glaucoma, in whom pressure-independent factors may play a relatively larger role in disease progression. These agents would target risk factors and underlying pathophysiologic mechanisms of disease other than IOP.[7,10,24]

Pathophysiology of Open-Angle Glaucoma

3 As stated previously, optic nerve damage in POAG can occur at a wide range of IOPs, and the rate of progression is highly variable. Patients may exhibit pressures in the 20 to 30 mm Hg (2.7-4.0 kPa) range for years before any disease progression is noticed in the optic disk or visual fields. That is why POAG is often referred to as the “sneak thief of sight.”

Clinical Presentation of Open-Angle Glaucoma

POAG is a bilateral, often asymmetric, genetically determined disorder constituting 60% to 70% of all glaucomas and 90% to 95% of primary glaucomas in the United States (see the “Clinical Presentation” box). An increased IOP is not required for diagnosis of POAG. Symptoms do not present until substantial visual field constriction occurs. Central visual acuity typically is maintained, even in the late stages of the disease. Even though POAG is a bilateral disease, it may have greater IOP and progression and severity in one eye. As such, each eye is treated individually.[7]

4 Detection and diagnosis involve evaluation of the optic disk and retinal nerve fiber layer, assessment of the visual fields, and measurement of IOP. The presence of characteristic disk changes and visual field loss with or without increased IOP confirms the diagnosis of glaucoma. Typical disk changes and field loss occurring at an IOP of less than 21 mm Hg (2.8 kPa) account for 20% to 30% of patients and are referred to as *normal-tension glaucoma*. Elevated IOP (>21 mm Hg [2.8 kPa]) without disk changes or visual field loss is observed in 5% to 7% of individuals (*glaucoma suspects*) and is referred to as *ocular hypertension*. New technologies such as OCT, retinal nerve fiber analyzers, or confocal scanning laser tomography of the optic nerve head may allow early identification of signs of glaucomatous retinal changes in ocular hypertensives, thus allowing for earlier initiation of therapy.[7]

Secondary OAG has many causes, including exfoliation syndrome, pigmentary glaucoma, systemic diseases, trauma, surgery, ocular inflammatory diseases, and medications. A system for classifying secondary glaucomas into pretrabecular, trabecular, and posttrabecular forms has been proposed. This classification allows drug therapy to be chosen on the basis of the pathogenic mechanism involved. In pretrabecular forms, a normal meshwork is covered and does not permit aqueous humor outflow. Trabecular forms of secondary glaucoma result from either an alteration of meshwork or an accumulation of material in the intertrabecular spaces. The posttrabecular forms result primarily from disorders causing increased episcleral venous blood pressure.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Glaucoma

General

- Glaucoma can be detected in otherwise asymptomatic patients, or patients can present with characteristic symptoms, especially vision loss. POAG is a chronic, slowly progressive disease found primarily in patients older than 50 years, whereas PACG is more typically associated with symptomatic acute episodes or may be slowly progressive like POAG

Symptoms

- POAG: None until substantial visual field loss occurs
- PACG: Nonsymptomatic or prodromal symptoms (blurred or hazy vision with halos around lights that is caused by a hazy, edematous cornea, and occasionally headache) may be present. Acute episodes produce symptoms associated with a cloudy, edematous cornea, ocular pain, or discomfort, nausea, vomiting, abdominal pain, and diaphoresis

Signs

- POAG: Disk changes and visual field loss (see Table 114-2); IOP can be normal or elevated (>21 mm Hg [2.8 kPa])
    - Mild: Optic disk abnormalities with normal visual field with standard perimetry
- Moderate: Optic disk changes plus visual field abnormalities in one hemifield that are not within 5 degrees of central visual fixation
- Severe: Optic disk changes with visual field loss in both hemifields and loss within 5 degrees of central fixation and abnormalities in at least one hemifield
- Acute Angle-Closure Glaucoma (ACG): Acute, hyperemic conjunctiva, cloudy cornea, shallow anterior chamber, and occasionally an edematous and hyperemic optic disk; IOP is generally elevated markedly (40-90 mm Hg [5.3-12.0 kPa]) when symptoms are present
- Chronic (CACG): Disk changes and visual field loss (see Table 114-2); IOP can be normal or elevated (>21 mm Hg [2.8 kPa])

Laboratory Tests

- None

Other Diagnostic Tests

- Emerging tests include optical coherence tomography, retinal nerve fiber analyzers, and confocal scanning laser tomography of the optic nerve. Pachymetry is crucial to detect a thin cornea that has been proved to be associated with visual field progression in open-angle glaucomas

Prognosis of Open-Angle Glaucoma

⑤ In most cases of POAG, the overall prognosis is excellent when it is discovered early and treated adequately. Even patients with advanced visual field loss can have continued visual field loss reduced if the IOP is maintained at low enough pressures (often <10-12 mm Hg [1.3-1.6 kPa]). Medications will control IOP successfully in 60% to 80% of patients over a 5-year period. Progression of visual field loss still occurs in 8% to 20% of patients despite reaching standard therapy IOP goals. However, for untreated patients and for those who fail to achieve target IOP reduction, up to 80% have continued visual field loss. Estimates of progression to bilateral blindness in treated patients range from 4% to 22%. Compared to placebo, each 1 mm Hg (0.1 kPa) in IOP reduction reduces the risk of disease progression by at least 10% and up to 19%.[7,24] After 2 years, visual field loss occurred in 25.6% of placebo patients compared to 15.2% of those treated with latanoprost.[25] Thus, the keys to medical treatment of POAG are an effective, well-tolerated drug regimen, close monitoring of therapy, and adherence.[26,27]

Epidemiology of PACG

The incidence of PACG varies by the ethnic group, with a higher incidence in individuals of Inuit, Chinese, and Asian-Indian descent. Incidence rates of 1% to 4% have been reported in these populations.[7] Because of the high frequency of PACG in populous Asia, PACG accounts for approximately one-third of glaucoma worldwide. PACG accounts for a disproportionately high proportion of blindness (estimated at up to 50%) worldwide.[28-30]

Etiology Primary Angle-Closure Glaucoma (Acute ACG and CACG)

In North America, PACG accounts for a minority of cases of primary glaucoma. When severe acute angle-closure glaucoma (ACG) occurs, it may need to be treated as an emergency to avoid visual loss. PACG results from mechanical blockage of the (usually normal) trabecular meshwork by the peripheral iris. Partial or complete blockage of the meshwork occurs intermittently, potentially resulting in extreme fluctuations between normal IOP with no symptoms and very high IOP with symptoms of acute PACG. Between attacks of PACG, the IOP is usually normal unless the patient has concomitant POAG or nonreversible blockage of the meshwork with synechiae ("creeping" angle closure) that develops over time in the narrow-angle eye. PACG occurs in patients with inherited shallow anterior chambers (often seen in small eyes), which produce a narrow angle between the cornea and iris or tight contact between the iris and lens (pupillary block) (see Fig. 114-1C). The presence of a narrow angle is determined mainly by visualization of the angle by gonioscopy. Other tests for PACG involve provocation of an angle-closure–induced IOP increase. These tests, which attempt to produce angle closure through mydriasis (darkroom test or mydriasis test) or gravity (prone test), are rarely performed in the clinical setting.

Two major types of classic, reversible PACG have been described: PACG with pupillary block and PACG without pupillary block. PACG with pupillary block results when the iris is in firm contact with the lens. This produces a relative block of aqueous flow through the pupil to the anterior chamber (pupillary block), resulting in a bowing forward of the iris, which blocks the trabecular meshwork. PACG with pupillary block occurs most commonly when the pupil is in mid-dilation. In this position, the combination of pupillary block and relaxed iris allows the greatest bowing of the iris; however, angle closure may occur during miosis or mydriasis.

PACG can occur without significant pupillary block for patients with an abnormality called a *plateau iris*. The ciliary processes in these cases are situated anteriorly, which indent the iris forward and cause closure of the trabecular meshwork, especially during mydriasis. The mydriasis produced by anticholinergic drugs or any other drug results in precipitation of both types of PACG glaucoma, whereas drug-induced miosis may produce pupillary block.[7,30]

Pathophysiology of PACG

The mechanism of IOP elevation in PACG is clearer than that of POAG. In PACG, a physical blockage of trabecular meshwork is present. In many cases, single or multiple episodes of high IOP that in some patients may exceed 40 mm Hg (5.3 kPa) and result in optic nerve damage. Very high IOP (>60 mm Hg [8.0 kPa]) may result in permanent loss of visual field within a matter of hours to days.

One type of CAG, known as "creeping" angle closure, occurs in patients with narrow angles in which the iris adheres to the trabecular meshwork and may result in continuously increased IOP in ranges more similar to those of POAG, and the clinical behavior is similar to POAG, with individuals differing in the degree and rapidity of visual loss from any given elevated IOP.[30]

Clinical Presentation of Angle-Closure Glaucoma

Most patients with untreated PACG typically experience intermittent nonsymptomatic or prodromal symptoms brought on by precipitating events (see the "Clinical Presentation" box). Increased IOP during such prodromal episodes is not great enough or long enough to produce the other symptoms of a full-blown attack. Such prodromal attacks last 1 to 2 hours, at which time pupillary block is broken by further mydriasis or miosis, or when miosis or mydriasis occurs in patients with plateau iris. The rate at which IOP increases may be a determinant of when full-blown symptoms occur. Visual fields demonstrate generalized constriction or typical glaucomatous defects as seen in POAG. In approximately 25% of patients, severe attacks may occur, and if prolonged, total loss of vision may occur if the IOP is high enough. Tonometry reveals IOPs as high as 40 to 90 mm Hg (5.3-12.0 kPa). Patients who have developed adhesions between the iris and meshwork (anterior synechiae) may have chronic IOP elevation with intermittent spikes of high IOP when angle closure occurs.[7,30]

Drug-Induced Glaucoma

A number of medications are associated with increased IOP or carry labeling that cautions against use of the medication in glaucoma patients. The potential for a medication to produce or worsen glaucoma depends on the type of glaucoma and whether the patient is treated adequately.[7,31-35] Patients with treated, controlled POAG are at minimal risk of induction of an increase in IOP by systemic medications with anticholinergic properties or vasodilators; however, for patients with untreated glaucoma or uncontrolled POAG, the potential of these medications to increase IOP should be considered. Topical anticholinergic agents used to produce mydriasis may result in an increase in IOP. Potent anticholinergic agents such as atropine or homatropine are most likely to increase IOP. Weaker anticholinergics, such as tropicamide, that produce less cycloplegia are less likely to increase IOP and are favored, along with phenylephrine, when mydriasis is desired for POAG patients. Inhaled, nasal, topical, or systemic glucocorticoids may increase IOP for both normal individuals and patients with POAG.

Patients with POAG appear to be particularly susceptible to glucocorticoid-induced increases in IOP. Glucocorticoids reduce the facility of aqueous humor outflow through the trabecular meshwork. The decreased facility of outflow appears to result from the accumulation of extracellular material blocking the trabecular channels. The potential of a glucocorticoid to increase IOP is related to its anti-inflammatory potency and intraocular penetration. Thus, patients should be treated with the lowest potency and dose and for the shortest time possible when steroids are indicated.

For patients predisposed to CAG (ie, narrow anterior chambers), angle closure may be produced by any drug that causes mydriasis (eg, anticholinergics). A wide range of sulfa compounds causes idiosyncratic reactions that result in lens swelling and anterior choroidal effusions with anterior movement of the iris and lens, resulting in angle closure. The topical use of anticholinergics or sympathomimetic agents most likely will result in angle closure. Systemic and inhaled anticholinergic and sympathomimetic agents also must be used with caution in such patients. As discussed previously, potent miotic agents such as echothiophate may produce angle closure by increasing pupillary block. Table 114-3 lists the drugs associated with potentiation of glaucoma.

TABLE 114-3

Drugs That May Induce or Potentiate Increased Intraocular Pressure

Open-angle glaucoma Ophthalmic corticosteroids (high risk) Systemic corticosteroids Nasal/inhaled corticosteroids Fenoldopam Ophthalmic anticholinergics Succinylcholine Vasodilators (low risk) Cimetidine (low risk)
Closed-angle glaucoma Topical anticholinergics Topical sympathomimetics Systemic anticholinergics Heterocyclic antidepressants Low-potency phenothiazines Antihistamines Ipratropium Benzodiazepines (low risk) Theophylline (low risk) Vasodilators (low risk) Systemic sympathomimetics (low risk) CNS stimulants (low risk) Serotonin-selective reuptake inhibitors Imipramine Venlafaxine Topiramate Tetracyclines (low risk) Carbonic anhydrase inhibitors (low risk) Monoamine oxidase inhibitors (low risk) Topical cholinergics (low risk)

TREATMENT

Treatment for Glaucoma Suspect and Ocular Hypertension

Treatment of the patients with possible glaucoma (ocular hypertension; ie, patients with IOP >22 mm Hg [2.9 kPa]) is less controversial with the recent results of the Ocular Hypertensive Treatment Study (OHTS) than it was in the past.[10] The OHTS helped to identify risk factors for treatment. Patients with IOPs higher than 25 mm Hg (3.3 kPa), vertical cup-to-disk ratio of more than 0.5, and central corneal thickness of less than 555 µm are at greater risk for developing glaucoma. Risk factors such as family history of glaucoma, Black, Latino/Hispanic ethnicity, severe myopia, and patients with only one eye must also be taken into consideration when deciding which individuals need treatment.

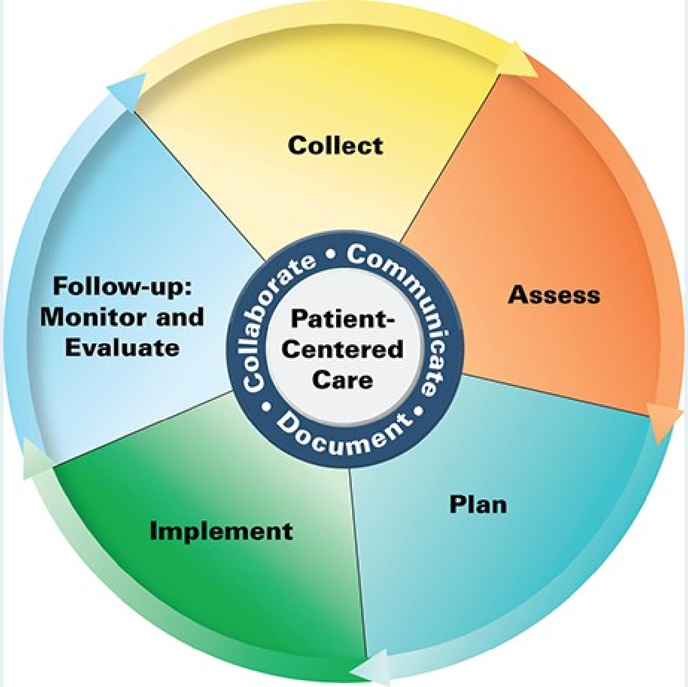
Patients without risk factors typically are not treated and are monitored for the development of glaucomatous changes. The use of risk calculators has been suggested as a means of determining who are at greatest risk in developing glaucoma. It is hoped that with future improvement in such calculators, one would be able to tailor treatment to those at greatest risk for developing glaucoma.

Patients with significant risk factors usually are treated with a well-tolerated topical agent such as a prostaglandin analog or β-blocking agent. Other options include a α_2-agonist (brimonidine), a topical carbonic anhydrase inhibitor (CAI), or netarsudil, depending on individual patient characteristics. Therapy may be initiated in one eye to assess tolerance and efficacy compared to the contralateral eye; however, because each eye may respond differently to a medication as well as possible contralateral effects, IOP response may be compared to baseline in individual eyes.

The goal of therapy is to lower the IOP to a level associated with a decreased risk of optic nerve damage, usually at least a 20%, if not a 25% to 30% decrease from the baseline IOP. Greater decreases may be required in high-risk patients or those with higher initial IOPs. Drug therapy should be monitored by measurement of IOP, examination of the optic disk, assessment of the visual fields, and evaluation of the patient for drug adverse effects and compliance with therapy. Patients who are unresponsive to or intolerant of a drug should be switched to an alternative agent rather than given an additional drug. Partial responders may be treated with combinations of well-tolerated topical medications (prostaglandins, beta-blockers, brimonidine, or a CAI). The use of multiple combinations of topical agents or when first-line agents fail to reduce IOP depends on the risk-to-benefit assessment of each patient. Some clinicians prefer to discontinue all medications for patients who fail to respond adequately to simple topical therapy, closely monitor for the development of disk changes or visual field loss, and treat again when such changes occur. The cost and inconvenience of frequent adverse effects of multiple-combination therapies, pilocarpine, cholinesterase inhibitors, and oral CAIs generally result in an unfavorable risk-to-benefit ratio for glaucoma suspect patients.[3,4,7,32-34,36,37]

PATIENT CARE PROCESS

Patient Care Process for the Management of Glaucoma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, and pregnant)
- Patient history (past medical, family history of glaucoma, social, and date and results of past eye examinations)
- Changes in vision (see Fig. 114-2)

- Current medications, including nonprescription agents and topically applied products, including eye drops (see Table 114-3 for agents that affect intraocular pressure [IOP])
- Objective data (see the "Clinical Presentation" box)
    - IOP measurements
    - Disc changes and abnormalities—bilateral, symmetrical?
    - Visual field changes and losses

Assess

- If PACG is suspected, manage or refer as ophthalmologic emergency
- Presence of conditions that can produce secondary cases of open-angle glaucoma (eg, exfoliation syndrome, pigmentary glaucoma, systemic diseases, trauma, surgery, ocular inflammatory diseases, and medications [see Table 114-3])
- Current medications that may contribute to or worsen glaucoma (see Table 114-3)
- Past history of adverse effects to agents used in the treatment of glaucoma
- Identify target IOP goal based on past history and current situation

Plan[*]

- Drug therapy regimen designed to achieve target IOP, including specific agent(s), dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Fig. 114-3 and Table 114-4)
- Monitor IOP for target reductions (usually at least 20% reduction from baseline IOP, if not a reduction of 25% to 30%, at 4 to 6 weeks after therapy begins, and for adverse effects [eg, local intolerance or reactions, altered iris pigmentation within 2 years of treatment initiation, hypertrichosis, hyperpigmentation of lids or lashes]
- Referrals to other providers when appropriate (eg, ophthalmologist)

Implement[*]

- Provide patient education regarding all elements of treatment plan
- Provide extensive education about administration of eye drops, separation of doses, and reinforcement of importance of adherence to preservation of vision
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, usually 4 to 6 weeks after therapy starts and every 3 to 4 months once target IOPs are achieved

Follow-up: Monitor and Evaluate

- Measure IOP
- Optic disc and visual fields
- Adverse effects to medications
- Adherence to treatment and drug administration technique

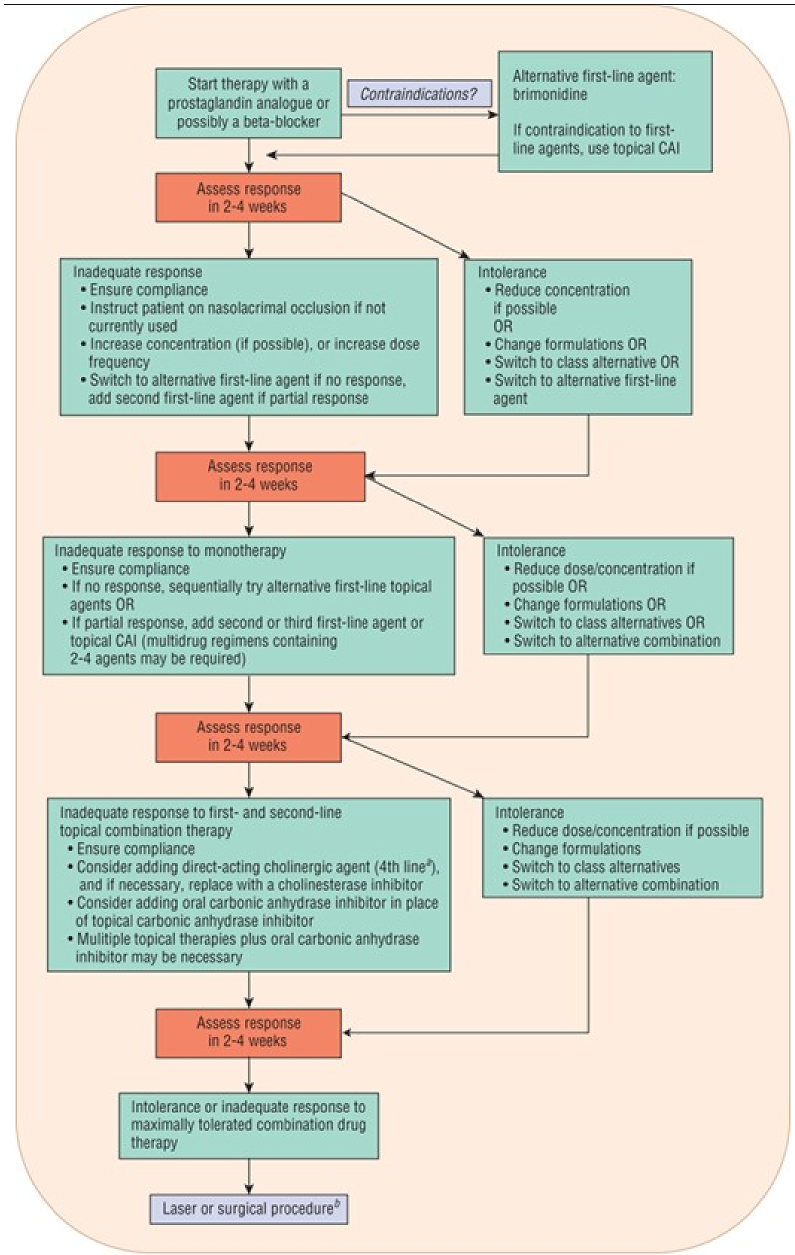
[*] *Collaborate with patient, caregivers, and other healthcare professional.*

Treatment for Open-Angle Glaucoma

All patients with elevated IOP and characteristic optic disk changes and/or visual field defects not caused by other factors (ie, glaucoma by definition) should be treated. Recent findings that one in five patients with “normal” IOP and glaucomatous retinal nerve findings (ie, normal-tension glaucoma) do not have progression of visual field loss if left untreated have prompted recommendations to monitor normal-tension glaucoma patients without immediate threat of loss of central vision and to treat only when progression is documented. Some controversy exists as to whether the initial therapy of glaucoma should be surgical trabeculectomy (filtering procedure), argon or selective laser trabeculectomy, or medical therapy.[7,32-34,36-43] Drug therapy remains the most common initial treatment modality. Drug therapy of patients with documented glaucomatous change with either elevated or normal IOP is initiated in a stepwise manner (Fig. 114-3), starting with a single, well-tolerated topical agent. The goal of therapy is to prevent further visual loss. A “target” IOP is chosen based on a patient baseline IOP and the amount of existing visual field loss. Typically, an initial target IOP reduction of 25% to 30% is desired. Greater reductions may be desired for patients with very high baseline IOPs or advanced visual field loss. Patients with normal baseline IOPs (normal-tension glaucoma) may have target IOPs of less than 10 to 12 mm Hg (1.3-1.6 kPa).[7]

FIGURE 114-3

Algorithm for the pharmacotherapy of open-angle glaucoma. [a]Fourth-line agents are not commonly used any longer or are commercially unavailable. [b]Most clinicians believe the laser procedure should be performed earlier (eg, after three-drug maximum, poorly adherent patient). (CAI, carbonic anhydrase inhibitor.)



Start therapy with a prostaglandin analogue or possibly a beta-blocker
Contraindications?
Alternative first-line agent: brimonidine
If contraindication to first-line agents, use topical CAI
Assess response in 2-4 weeks
Inadequate response
• Ensure compliance
• Instruct patient on nasolacrimal occlusion if not currently used
• Increase concentration (if possible), or increase dose frequency
• Switch to alternative first-line agent if no response, add second first-line agent if partial response
Intolerance
• Reduce concentration if possible OR
• Change formulations OR
• Switch to class alternative OR
• Switch to alternative first-line agent
Assess response in 2-4 weeks
Inadequate response to monotherapy
• Ensure compliance
• If no response, sequentially try alternative first-line topical agents OR
• If partial response, add second or third first-line agent or topical CAI (multidrug regimens containing 2-4 agents may be required)
Intolerance
• Reduce dose/concentration if possible OR
• Change formulations OR
• Switch to class alternatives OR
• Switch to alternative combination
Assess response in 2-4 weeks
Inadequate response to first- and second-line topical combination therapy
• Ensure compliance
• Consider adding direct-acting cholinergic agent (4th line^a), and if necessary, replace with a cholinesterase inhibitor
• Consider adding oral carbonic anhydrase inhibitor in place of topical carbonic anhydrase inhibitor
• Mulitiple topical therapies plus oral carbonic anhydrase inhibitor may be necessary
Intolerance
• Reduce dose/concentration if possible
• Change formulations
• Switch to class alternatives
• Switch to alternative combination
Assess response in 2-4 weeks
Intolerance or inadequate response to maximally tolerated combination drug therapy
Laser or surgical procedure^b

Pharmacotherapeutic Approach

⑥ Medications most commonly used to treat glaucoma are the prostaglandin analogs, nonselective β-blockers, brimonidine (a α_2-agonist), the topical CAIs, and the fixed combination products of timolol/dorzolamide, timolol/brimonidine, brimonidine/brinzolamide, or timolol/prostaglandins (non-United States). Effective and acceptable safety profiles include latanoprostene bunod and netarsudil.[7,32-34,36,37]

The prostaglandin analogs are often recommended as first-line therapy. They offer once-daily dosing, better IOP reduction, better 24-hour IOP control, good tolerance, and availability of lower-cost generics (see Fig. 114-3). The topical β-blockers have a long history of successful use, providing a combination of clinical efficacy and general tolerability. Brimonidine and topical CAIs are also well tolerated and effective agents, but often considered second-line agents (to prostaglandins and beta blockers).[7] The role of newer agents such as latanoprostene bunod and netarsudil are not established but will likely be used (individually or in combination) in patients not inadequately responding to or intolerant of other agents. Therapy optimally is started as a single agent; it can be started in one eye (except for patients with very high IOP or advanced visual field loss) to evaluate drug efficacy and tolerance, although response may differ between contralateral eyes. Monitoring of therapy should be individualized. Initial check for IOP response to therapy is typically done 4 to 6 weeks after the medication is started. Once IOPs reach acceptable levels, the IOP is monitored every 3 to 4 months or longer if there is prolonged control (over 6-12 months) without progression. More frequent monitoring is necessary if IOP target is not achieved, disease progression is noted, and after any change in drug therapy.[7]

Visual fields and disk changes are typically monitored every 6 to 12 months or earlier if the glaucoma is unstable or there is suspicion of disease worsening. Patients should always be questioned regarding adherence to and tolerance of prescribed therapy. Initial IOP response does not predict long-term IOP control, as tachyphylaxis to IOP reduction and or disease progression may occur.

The value of an agent with which the patient has shown a drop in IOP following an initial response can be measured by discontinuing the medication completely and determining if an increase in IOP occurs. Patients responding to but intolerant of initial therapy may be switched to another drug. For patients failing to respond to an initial drug, a switch to an alternative agent should be considered. If only a partial response occurs, addition of another topical drug to be used in combination is a possibility. A number of drugs or drug combinations may need to be tried before an effective and well-tolerated regimen is identified. Prostaglandin agonists, beta blockers, brimonidine, CAI, and pilocarpine may be used in various combinations. Generally adding a second drug results in a less than additive reduction in IOP. Using more than one drop per dose does not improve response, and it increases the likelihood of adverse effects and the cost of therapy. When using more than one medication, separation of drop instillation of each agent by at least 5 minutes is suggested to provide optimal ocular absorption. Combination products reduce the number of daily doses, possibly improving adherence and preventing washout effect seen when a second medication is administered too soon after the initial medication. The use of combination products also reduces exposure to ophthalmic preservatives. Ocular surface disease (OSD) secondary to glaucoma therapy will often manifest as superficial punctate keratitis, tear-film instability, or allergy.[44] In-vivo and animal studies have demonstrated the toxic effects of preservatives, often benzalkonium chloride through various mechanisms. However, extrapolating these results to clinical use is difficult because these studies must control for effects such as blinking, tear dilution and turn over, buffering capabilities, etc., of the human eye. While many crossover clinical trials show benefit to preservative-free therapies, there are a multitude that demonstrate no improvement. Patients with medication-related OSD may try treatment with artificial tears, anti-inflammatory therapy, or possibly preservative-free therapy if feasible.

The IOP response to ocular hypotensive medication may vary with corneal thickness. The response might be better in those with normal or thin corneas than in those with thicker structures.

Because of the frequency of adverse effects, carbachol, topical cholinesterase inhibitors, and oral CAIs are considered last-line agents to be used for patients who fail less-toxic combination topical therapy.

Nonpharmacologic Therapy: Laser and Surgical Procedures

When drug therapy fails, is not tolerated, or is excessively complicated, surgical procedures such as laser trabeculoplasty (argon or selective) or a surgical trabeculectomy (filtering procedure) may be performed to improve outflow. Laser trabeculoplasty is usually an intermediate step between drug therapy and trabeculectomy. The newer selective laser trabeculoplasty (SLT) procedure has demonstrated similar IOP reduction as argon laser trabeculoplasty (ALT) and may be repeatable. Recent studies have demonstrated good efficacy for this procedure in comparison with medical treatment options for POAG.

A multicenter randomized clinical trial (LiGHT Study) conducted at six hospitals in the United Kingdom compared the use of eye drops versus the use of selective laser trabeculoplasty as a first-line treatment in patients with POAG or OHT.[45] The primary outcome was health-related quality of life (HRQoL) at 3 years. Secondary outcomes were cost and cost-effectiveness, disease-specific HRQoL, clinical effectiveness, and safety. Of the patients in the SLT group, 74.2% (95% CI 69.3-78.6) required no eye drops at 36 months to maintain IOP at target. IOPs within the target range were achieved in slightly more eyes of those in the SLT group (93.0%) than among those using eye drops (91.3%). Glaucoma surgery was needed for 11 patients in the eye drops group versus none of those who received SLT initially. The HRQoL and cost-effectiveness were also more favorable in the SLT group.[45,46]

A real-world outcomes study in the United Kingdom assessed baseline factors associated with treatment success in patients undergoing their first recorded SLT. The main outcome measures were change from baseline in IOPs and glaucoma medication use with failure defined as any further glaucoma procedure post-SLT or IOP of greater than 21 mm Hg (2.8 kPa), IOP reduction of less than 20%, or an increase in glaucoma medications from baseline. The majority failed SLT within 1 year, and efficacy was better in patients with higher baseline IOP but did not differ by glaucoma severity or concurrent use of IOP-lowering medication.[46] As these studies show, many factors must be considered for patients with glaucoma when choosing a laser treatment option.

Procedures with higher complication rates, such as those involving placement of draining tubes or destruction of the ciliary body (cyclodestruction), may be required when other methods fail (see Figs. 114-1 and 114-2).[7]

Surgical methods for reduction of IOP involve the creation of a channel through which aqueous humor can flow from the anterior chamber to the subconjunctival space (filtering bleb), where it is reabsorbed by the vasculature. A major reason for failure of the procedure is healing and scarring of the site. The use of aqueous shunts or valves to manage glaucoma has been increasing, and the results of a recent study have demonstrated improved safety and efficacy of these devices. However, glaucoma surgery is still plagued with the shortcomings despite modifications and improvements over the past century, including potentially vision-threatening complications like hypotony, wound leaks, and infections.[40,41,47] MIGS (Minimally Invasive Glaucoma Surgery) offers micro incisions and implants that reduce IOP by targeting various areas of the outflow pathway.[47] These can be approached from either inside the eye (ab-interno) (eg, iStent, Hydrus, Trabectome, XEN 45, suprachoroidal shunts) or outside the eye (ab-externo) (eg, canaloplasty, Gold micro shunt, and Stegman Canal Expander).[47] MIGS can be considered as an alternative to medical therapy in an effort to address adherence challenges, adverse events, and quality-of-life (QOL) issues with topical medications. They are usually performed in combination with cataract surgery (eg, iStent, Hydrus) or as a solo procedure (XEN 45).

Modification of the healing process to maintain patency is possible with the use of antiproliferative agents. The antiproliferative agents, 5-fluorouracil and mitomycin C, are used for patients undergoing glaucoma-filtering surgery to improve success rates by reducing fibroblast proliferation and consequent scarring. Although used most commonly for patients with increased risk for suboptimal surgical outcome (after cataract surgery and a previous failed filtering procedure), the use of these agents also improves success in low-risk patients.[40,41,47] A standardized formulation of mitomycin C (MMC) that is prepacked in a kit with a fixed dose and concentration was approved by the US Food and Drug Administration in 2012 and is commercially available under the name “Mitosol.” Off-label use of mitomycin C prepared by compounding pharmacies is also common.

Treatment for Acute Angle-Closure Crisis (AACC)

The goal of initial therapy for acute AACC with high IOP is rapid reduction of the IOP to preserve vision and to avoid surgical or laser iridectomy on a hypertensive, congested eye. Iridectomy (laser or surgical) is the definitive treatment of PACG; it produces a hole in the iris that permits aqueous humor flow to move directly from the posterior chamber to the anterior chamber, opening up the block at the trabecular meshwork. Drug therapy of an AACC typically involves administration of one or more topical antiglaucoma medications including miotics (eg, pilocarpine), secretory inhibitors (β-blockers, α_2-agonist, or topical/systemic CAIs), or a prostaglandin agonist.[6,30] The miosis produced by pilocarpine pulls the peripheral iris away from the meshwork. However, miotics may worsen angle closure by increasing pupillary block and producing anterior movement of the lens because of drug-induced accommodation. The aqueous secretory inhibitors and pilocarpine may not be effective due to ischemia of the ciliary body and pupillary sphincter, respectively. Now, the urge to use excessive amounts of topical agents must be resisted. A hyperosmotic agent such as mannitol or glycerin may be needed to temporarily reduce IOP and restore response to the topical agents.

An osmotic agent also is commonly administered because these drugs produce the most rapid decrease in IOP. Oral glycerin 1 to 2 g/kg can be used if an oral agent is tolerated; if not, IV mannitol 1 to 2 g/kg should be used. Osmotic agents reduce IOP by withdrawing water from the eye secondary to the osmotic gradient between the blood and the eye. These drugs are among the first-line agents in the short-term treatment of an AACC or other forms of acute very high IOP elevations. Topical corticosteroids often are used to reduce the ocular inflammation and reduce the development of synechiae in PACG eyes. Patients failing therapy altogether will require an emergency iridectomy. Once the IOP is controlled, iridectomy is performed on the affected eye as well as the contralateral eye (if narrow angles are present). As reported in the EAGLE study, for patients who are older than 50 years and with other specific inclusion criteria, an alternative approach involves crystalline lens extraction since it plays a role in PACG pathology.[48]

Laser peripheral iridotomy can prevent acute angle closure glaucoma in patients at risk. However, its role on preventing the conversion of an angle-closure suspect to PACG is modest.[31,49] Long-term drug therapy is not used unless IOP remains high because of the presence of synechiae blocking the trabecular meshwork or concurrent POAG. In such cases, the pharmacotherapeutic approach is essentially identical to that for the POAG patient, or laser or surgical procedures are performed.[30]

PHARMACOLOGIC AGENTS USED IN GLAUCOMA

Prostaglandin Analogs

The prostaglandin analogs, including latanoprost, travoprost, bimatoprost, and tafluprost, reduce IOP by increasing the uveoscleral and, to a lesser extent, trabecular outflow of aqueous humor. Some differences in receptor sites and mechanisms of action may exist between the two prostaglandins (latanoprost, travoprost, and tafluprost) and the prostamide (bimatoprost). However, both classes appear to produce collagen changes in the matrix of the ciliary body and trabecular meshwork. Bimatoprost may be slightly more effective in lowering IOP, getting a larger percentage of patients to lower IOPs, and for patients unresponsive to latanoprost. If the patient does not respond to one prostaglandin agonist, a switch to another may be beneficial.[39,42,50] Generic forms of some prostaglandin analogs are now available, reducing the cost to patients for these agents. Tafluprost is available as a preservative-free solution, which may be useful in patients intolerant of common ophthalmic preservatives or those with corneal surface disorders.

Reduction in IOP with once-daily doses of prostaglandin analogs (a 25%-35% reduction) is often greater than that seen with timolol 0.5% twice daily. In addition, nocturnal control of IOP is improved compared with timolol.[7,42,50] The drugs are administered at nighttime, although they are probably as effective if given in the morning.

Prostaglandin analogs are well tolerated and produce fewer systemic adverse effects than timolol. Local ocular tolerance generally is good, but ocular reactions such as punctate corneal erosions and conjunctival hyperemia do occur. Local intolerance occurs in 10% to 25% of patients with these agents.[7,33,36,37,51]

With prostaglandin analogs, altered iris pigmentation occurs in 15% to 30% of patients, particularly those with mixed-color irises (blue-brown, green-brown, blue-gray-brown, or yellow-brown eyes), which become browner in color over 3 to 12 months. The change in iris pigmentation will often appear within 2 years, and long-term consequences of this pigment change appear to be mostly cosmetic but irreversible upon discontinuation. Hypertrichosis is common and reverses upon discontinuation of the drug. Hyperpigmentation around the lids and lashes has also been reported and appears to reverse upon discontinuation. Loss of periorbital fat has been reported, which may lead to apparent enophthalmos and sunken eye, especially when used unilaterally.

Topical prostaglandin analogs may produce rates of corneal thinning that are slightly higher than ongoing age-related changes. This effect is unlikely to be clinically relevant.[24,33,36,37,51,52]

These agents have occasionally been associated with uveitis, and caution is recommended for patients with ocular inflammatory conditions. Cases of cystoid macular edema and worsening of herpetic keratitis have been reported.

Prostaglandin analogs can be used in combination with other antiglaucoma agents for additional IOP control because of their unique mechanism of action. Given their excellent efficacy and side-effect profile, prostaglandin analogs provide effective monotherapy or adjunctive therapy for patients who are not responding to or tolerating other agents. Long-term studies demonstrate that these agents are safe, efficacious, and well tolerated in glaucoma therapy.[24,33,36,37,51,52] Various fixed combination prostaglandin products, often with timolol, are available in Canada and overseas.

Latanoprostene bunod is a newer agent approved for use in patients with OAG and OHT.[50,51,53] This agent is a prodrug of latanoprost and is also metabolized to a nitric-oxide–donating moiety, thus providing dual mechanisms for increasing aqueous outflow. This agent produces IOP reduction similar to or greater than that with timolol. Adverse effects are similar to that seen with pure prostaglandin analogs.

The first intraocular biodegradable, implant of bimatoprost (Durysta), is another newer product indicated for patients with OAG and OHT. It is administered intracamerally (into the anterior chamber of the affected eye). The bimatoprost implant has potential to improve adherence and reduce treatment burden in glaucoma. In a randomized, 20-month, evaluator-masked, phase 3 clinical study, efficacy (IOP lowering) and safety of bimatoprost 10- and 15-mcg implants were evaluated. Bimatoprost implants 10 mcg (n = 198) or 15 mcg (n = 198) on day 1 were noninferior to timolol in IOP lowering after administration at baseline and weeks 16 and 32 of the trial. Corneal and inflammatory treatment-emergent adverse events of interest (eg, corneal endothelial cell loss, iritis) were higher with bimatoprost implants than timolol and highest with the 15-μg dose implants. One year after the third administration of bimatoprost implants, IOP was controlled in most study participants. The risk-benefit assessment favored the commercial approval for the 10-mcg implant, and the US Food and Drug Administration approved that dose for a single administration in each eye for the life of the patient. Ongoing studies are evaluating other administration regimens.[26,47] The bimatoprost implant has potential for improving adherence and reducing treatment burden in glaucoma.

β-Blocking Drugs

The topical β-blocking agents are one of the most commonly used antiglaucoma medications (Table 114-4). β-Blockers lower IOP by 20% to 30% with a minimum of local ocular adverse effects. Beta blockers have minimal effects on nocturnal IOP. These are commonly one of the agents of first choice—along with prostaglandin analogs—in treating POAG if no contraindications exist.[7,33,36,37,51]

TABLE 114-4

Topical Drugs Used in the Treatment of Open-Angle Glaucoma

Drug	Pharmacologic Properties	Common Brand Names/Generic	Dosage Form	Strength (%)	Usual Dose[a]	Mechanism of Action
β-Adrenergic blocking agents						
Betaxolol	Relative β_1 selective	Generic	Solution	0.5	One drop twice a day	All reduce aqueous production of ciliary body
		Betoptic-S	Suspension	0.25	One drop twice a day	
Carteolol	Nonselective, intrinsic sympathomimetic activity	Generic	Solution	1	One drop twice a day	
Levobunolol	Nonselective	Betagan/Generic	Solution	0.25, 0.5	One drop twice a day	
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	One drop twice a day	
Timolol	Nonselective	Timoptic, Betimol, Istalol/Generic	Solution	0.25, 0.5	One drop every day—one to two times a day	

		Timoptic-XE/Generic	Gelling solution	0.25, 0.5	One drop every day[a]	
Adrenergic agonists						
α_2-Adrenergic agonists						
Apraclonidine	Specific α_2-agonists	Iopidine	Solution	0.5, 1	One drop two to three times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow; only brimonidine has primary indication
Brimonidine		Alphagan P 0.1/Generic 0.2, 0.15	Solution	0.2, 0.15, 0.1	One drop two to three times a day	
Cholinergic agonists direct acting						
Carbachol	Direct and indirect acting	Carboptic, Isopto Carbachol	Solution	1.5, 3	One drop two to three times a day[a]	All increase aqueous humor outflow through trabecular meshwork
Pilocarpine	Direct acting	Isopto Carpine, Pilocar/Generic	Solution	1, 2, 4	One drop two to three times a day[a]	
					One drop four times a day	
Cholinesterase inhibitors						
Echothiophate	Indirect acting cholinesterase inhibitor	Phospholine Iodide	Solution	0.125	Once or twice a	

					day	
Carbonic anhydrase inhibitors						
Topical						
Brinzolamide	Carbonic anhydrase type II inhibition	Azopt	Suspension	1	Two to three times a day	All reduce aqueous humor production of ciliary body
Dorzolamide		Trusopt/Generic	Solution	2	Two to three times a day	
Systemic						
Acetazolamide		Generic	Tablet	125 mg, 250 mg	125-250 mg two to four times a day	
		Injection	500 mg/vial	250-500 mg		
		Diamox Sequels	Capsule	500 mg	500 mg twice a day	
Methazolamide		Generic	Tablet	25 mg, 50 mg	25-50 mg two to three times a day	
Prostaglandin analogs						
Latanoprost	Prostanoid agonist	Xalatan/Generic	Solution	0.005	One drop every night	Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow
Latanoprostene Bunod	Prostanoid agonist	Vyzulta	Solution	0.024	One drop every night	
Bimatoprost	Prostamide	Lumigan	Solution	0.01, 0.03	One	

	agonist	0.01/Generic 0.03			drop every night	
		Durysta 10 mcg	Intracameral biodegradable implant	One implant per eye for the life of the patient		
Travoprost	Prostanoid agonist	Travatan Z/GenericTravoprost	Solution	0.004	One drop every night	
Tafluprost	Prostanoid agonist	Zioptan/Saflutan	Preservative free solution	0.0015	One drop every night	
Rho Kinase Inhibitors						
Netarsudil	Rho Kinase Inhibitor	Rhopressa	Solution	0.02	One drop every night	
Combinations						
Timolol–dorzolamide		Cosopt Generic	Solution	Timolol 0.5/Dorzolamide 2	One drop twice daily	
Timolol–brimonidine		Combigan	Solution	Timolol 0.5/Brimonidine 0.2	One drop twice daily	
Brinzolamide–brimonidine		Simbrinza	Suspension	Brinzolamide 1/Brimonidine 0.2	One drop three times daily

[a] Use of nasolacrimal occlusion will increase the number of patients. Successfully treated with longer dosage intervals.

The β-blocking agents produce ocular hypotensive effects by decreasing the production of aqueous humor by the ciliary body without producing substantial effects on aqueous humor outflow facility. The mechanism by which β-blockers decrease aqueous humor inflow remains controversial, but it is most frequently attributed to β_2-adrenergic receptor blockade in the ciliary body.

Five ophthalmic β-blockers are presently available: timolol, levobunolol, metipranolol, carteolol, and betaxolol. Timolol, levobunolol, and metipranolol are nonspecific β-blocking agents, whereas betaxolol is a relatively β_1-selective agent. Carteolol is a nonspecific blocker with intrinsic sympathomimetic activity. Despite differences in potency, selectivity, lipophilicity, and intrinsic sympathomimetic activity, the five agents reduce IOP to a similar degree, although betaxolol has been reported to produce somewhat less lowering of IOP than timolol and levobunolol. Levobunolol, which possesses alpha-adrenergic effects, may be more effective than timolol and betaxolol in reducing postcataract surgery IOP increases and may be more effective in controlling IOP than other agents when given as aqueous solutions on a once-daily schedule (up to 70% of patients). Timolol in the form of a gel-forming solution (Timoptic-XE) provides equivalent IOP control with once-daily administration when compared with the same concentration of the aqueous solution administered twice daily. The choice of a specific β-blocking agent generally is based on differences in adverse effect potential, individual patient response, and cost. Treatment with topical β-blockers may result in tachyphylaxis (short-term escape and long-term drift) in 20% to 25% of patients. The mean IOP reduction from baseline may be smaller for patients receiving topical β-blockers with concurrent systemic β-blockers.[33,36,37]

Local adverse effects with β-blockers usually are tolerable, although stinging on application occurs commonly, particularly with betaxolol solution (less with betaxolol suspension) and metipranolol. Other local effects include dry eyes, corneal anesthesia, blepharitis, blurred vision, and, rarely, conjunctivitis, uveitis, and keratitis. Some local reactions may be a result of preservatives used in the commercially available products. Switching from one agent to another or switching the type of formulation may improve tolerance in patients experiencing local adverse effects.

Systemic effects are the most important adverse effects of β-blockers. Drug absorbed systematically may produce decreased heart rate, reduced blood pressure, negative inotropic effects, conduction defects, bronchospasm, CNS effects, and alteration of serum lipids and may block the symptoms of hypoglycemia. The β_1-specific agents' betaxolol and possibly carteolol (as a consequence of intrinsic sympathomimetic activity) are less likely to produce the systemic adverse effects caused by β-adrenergic blockade, such as the cardiac effects and bronchospasm, but a real risk still exists. The use of timolol as a gel-forming liquid or betaxolol as a suspension allows for administration of fewer drugs per day and, therefore, reduces the chance for systemic adverse effects compared with the aqueous solutions.

Because of their systemic adverse effects, all ophthalmic β-blockers should be used with caution for patients with pulmonary diseases, sinus bradycardia, second- or third-degree heart block, congestive heart failure, atherosclerosis, diabetes, and myasthenia gravis, as well as for patients receiving oral β-blocker therapy. The use of the nasolacrimal occlusion (ELC; see Patient Education below for description) technique during administration reduces the risk or severity of systemic adverse effects, as well as optimizes response. Overall, β-adrenergic blocking agents are well tolerated by most patients, and most potential problems can be avoided by appropriate patient evaluation, drug choice, and monitoring of drug therapy. For patients failing or having an inadequate response to single-drug therapy with a β-blocking agent, the addition of a topical CAI, prostaglandin analog, or the α_2-adrenergic receptor agonist brimonidine usually will result in additional IOP reduction.[7,33,36,37,51]

α_2-Adrenergic Agonists

Brimonidine and the less lipid-soluble and less receptor-selective apraclonidine are α_2-adrenergic agonists structurally similar to clonidine. Apraclonidine is indicated and brimonidine is effective for prevention or control of postoperative or postlaser treatment increases in IOP. Brimonidine has a primary indication in open-angle glaucoma and is considered a second-line agent (often after a prostaglandin or beta blocker) or adjunctive agent. Apraclonidine is generally used only in short term after ocular surgery due to high incidence of loss of control of IOP (tachyphylaxis) and a more severe and prevalent ocular allergy rate.

Alpha-2 agonists reduce IOP by decreasing the rate of aqueous humor production (some increase in uveoscleral outflow also occurs with brimonidine). The drugs reduce IOP by 18% to 27% at peak (2-5 hours) and by 10% at 8 to 12 hours. Comparative trials demonstrate a reduction in IOP similar to that obtained with 0.5% timolol. The use of brimonidine 0.2% every 8 to 12 hours provides maximum IOP-lowering effects in long-term use. The use of ELC (see Patient Education below) may improve response and allow the longer dosing frequency (ie, every 12 hours). These agents have minimal effects on nocturnal IOP. Combinations of α_2-agonists with β-blockers, prostaglandin analogs, or CAIs produce additional IOP reduction.

An allergic-type reaction characterized by lid edema, eye discomfort, foreign-object sensation, itching, and hyperemia occurs in approximately 30% of patients with apraclonidine. Brimonidine produces this adverse effect in up to 8% of patients. This reaction commonly necessitates drug discontinuation. Systemic adverse effects with brimonidine include dizziness, fatigue, somnolence, dry mouth, and possibly a slight reduction in blood pressure and pulse. α_2-Agonists should be used with caution for patients with cardiovascular diseases, renal compromise, cerebrovascular disease, and diabetes, as well as in those taking antihypertensives and other cardiovascular drugs, monoamine oxidase inhibitors, and tricyclic antidepressants.

Brimonidine is also contraindicated in infants because of apneic spells and hypotensive reactions. In terms of overall efficacy and tolerability, brimonidine approximates that achieved with β-blockers.[7,33,36,37,51]

Brimonidine Purite 0.15% or 0.1% is a formulation of brimonidine in a lower concentration than the original product that contains a less corneal-toxic preservative than the commonly employed benzalkonium chloride. The newer formulations are as effective as the original because the more neutral pH of brimonidine Purite (0.15% pH 7.2; 0.1% pH 7.7) allows for higher concentrations of brimonidine in the aqueous humor with a similar reduction in IOP and a reduced incidence of ocular allergy.

A randomized clinical trial of topical brimonidine 0.2% twice daily preserved visual field better than treatment with topical timolol maleate 0.5% in patients with OAG and statistically normal IOP.[23] The IOP-lowering efficacy was similar between the two medications, suggesting that this finding was consistent with a non-IOP-related mechanism, possibly a neuroprotective action. However, validation of a neuroprotective role for brimonidine requires further research to confirm these results.[23,54] The combination product timolol 0.5% and brimonidine 0.2% (Combigan) may provide additional IOP lowering than either agent alone.

Carbonic Anhydrase Inhibitors

Topical Agents

CAIs reduce IOP by decreasing ciliary body aqueous humor secretion. CAIs appear to inhibit aqueous production by blocking active secretion of sodium and bicarbonate ions from the ciliary body to the aqueous humor.[7,33,51] The topical CAIs dorzolamide and brinzolamide are well tolerated and are considered second line (after prostaglandins and beta blockers) for monotherapy or adjunctive therapy of POAG and ocular hypertension. These drugs reduce IOP by 15% to 26%.

Topical CAIs generally are well tolerated. Local adverse effects include transient burning and stinging, ocular discomfort and transient blurred vision, tearing, and, rarely, conjunctivitis, lid reactions, and photophobia. A superficial punctate keratitis occurs in 10% to 15% of patients. Brinzolamide produces more blurry vision but is less stinging than dorzolamide. Systemic adverse effects are unusual despite the accumulation of drug in red blood cells. Because of their favorable adverse-effect profile, topical CAIs provide a useful alternative agent for monotherapy or adjunctive therapy for patients with inadequate response to or who are unable to use other agents. The drugs may add additional IOP reduction for patients using other single or multiple topical agents. The usual dose of a topical CAI is one drop every 8 to 12 hours. Administration every 12 hours produces somewhat less IOP reduction than administration every 8 hours. The use of ELC should optimize response to CAI given at any interval.[7,33] The combination product timolol 0.5% and dorzolamide 2% (Cosopt) is dosed twice daily and produces equivalent IOP lowering to each product dosed separately. Both dorzolamide and timolol/dorzolamide (Cosopt) are now available as generic formulations. The combination product brimonidine 0.2% and brinzolamide 1% (Simbrinza) is available dosed three times daily.

Systemic CAI Agents

Systemic CAIs are indicated for patients failing to respond to or tolerate maximum topical therapy. Systemic and topical CAIs should not be used in combination because no data exist concerning improved IOP reduction, and the risk for systemic adverse effects is increased. Oral CAIs reduce aqueous humor inflow by 40% to 60% and IOP by 25% to 40%. The available systemic CAIs (see Table 114-4) produce equivalent IOP reduction but differ for potency, adverse effects, dosage forms, and duration of action. Despite their excellent effects on elevated IOP of any etiology, the systemic CAIs frequently produce intolerable adverse effects. As a result, CAIs are considered third-line agents in the treatment of POAG and often used for short-term administration to lower IOP.

On average, only 30% to 60% of patients are able to tolerate oral CAI therapy for prolonged periods. Intolerance to CAI therapy results most commonly from a symptom complex attributable to systemic acidosis and including malaise, fatigue, anorexia, nausea, weight loss, altered taste, depression, and decreased libido. Other adverse effects include renal calculi, increased uric acid, blood dyscrasias, diuresis, and myopia. Elderly patients do not tolerate CAIs as well as younger patients. The available CAIs produce the same spectrum of adverse effects; however, the drugs differ in the frequency and severity of the adverse effects listed.

CAIs should be used with some caution in patients with sulfa allergies (all CAIs, topical or systemic, contain sulfonamide moieties, although cross-sensitivity is thought to be very low), sickle cell disease, respiratory acidosis, pulmonary disorders, renal calculi, electrolyte imbalance, hepatic disease, renal disease, diabetes mellitus, or Addison's disease. Concurrent use of a CAI and a diuretic may rapidly produce hypokalemia. High-dose salicylate therapy may increase the acidosis produced by CAIs, whereas the acidosis produced by CAIs may increase the toxicity of salicylates.[7,33,36,37,51]

Rho Kinase Inhibitors

Netarsudil is the first approved agent in a new class of antiglaucoma medications, Rho kinase inhibitors.[51,53] Netarsudil reduces IOP by increasing trabecular meshwork outflow. Once-daily (in the evening) administration of a 0.02% solution reduces both daytime and nighttime IOP. Efficacy appears to be similar to that of beta blockers. Netarsudil may be used in combination with other antiglaucoma agents. The most common local side effects are conjunctival hyperemia, conjunctival hemorrhage, and corneal verticillate. Systemic effects are rare. Patients with OAG or OHT who are taking as many as four ocular hypotensive medications showed modest IOP reduction when netarsudil was added to their regimen.[13]

A combination of netarsudil/latanoprost ophthalmic solution 0.02%/0.005% (Rocklatan) was approved in the United States. Rocklatan provided superior IOP reduction compared to either netarsudil or latanoprost products alone. However, discontinuation rates at 12 months occurred in 20.6%, 23.0%, and 1.7% of patients receiving netarsudil/latanoprost, netarsudil, and latanoprost, respectively.[28]

Parasympathomimetic Agents

The parasympathomimetic (cholinergic) agents reduce IOP by increasing aqueous humor trabecular outflow. The increase in outflow is a thought to be a result of physically pulling open the trabecular meshwork secondary to ciliary muscle contraction, thereby reducing resistance to outflow. These agents may actually reduce uveoscleral outflow. Their use as primary or even adjunctive agents in the treatment of glaucoma has decreased significantly because of local ocular adverse effects and/or frequent dosing requirements.

Pilocarpine, the parasympathomimetic agent of choice in POAG, is available as an ophthalmic solution (see Table 114-4). Pilocarpine produces similar (20%-30%) reductions in IOP as those seen with β-blocking agents. Pilocarpine in POAG is initiated as 1% solution, one drop three to four times daily. The use of ELC improves response and reduces the need for an every 6-hour dosing frequency. The use of one drop of 2% pilocarpine every 6 to 12 hours and ELC provides optimal response in many patients. Both drug concentration and frequency may be increased if IOP reduction is inadequate. Patients with darkly pigmented eyes frequently require higher concentrations of pilocarpine than do patients with lightly pigmented eyes. Concentrations of pilocarpine above 4% rarely improve IOP control in patients.

Ocular adverse effects of pilocarpine include miosis, which decreases night vision and vision in patients with central cataracts. Visual field constriction may be seen secondary to miosis and should be considered when evaluating visual field changes in a glaucoma patient. Pilocarpine ciliary muscle contraction produces accommodative spasm, particularly in young patients still able to accommodate (prepresbyopic). Pilocarpine may also produce frontal headache, brow ache, periorbital pain, eyelid twitching, and conjunctival irritation or injection early in therapy, which tends to decrease in severity over 3 to 5 weeks of continued therapy.

Cholinergics produce a breakdown of the blood–aqueous humor barrier and may result in a worsening of an ocular inflammatory reaction or condition. Systemic cholinergic adverse effects of pilocarpine such as diaphoresis, nausea, vomiting, diarrhea, cramping, urinary frequency, bronchospasm, and heart block can be seen. Other adverse effects associated with direct-acting miotics include retinal tears or detachment, allergic reaction, permanent miosis, cataracts, precipitation of CAG, and, rarely, miotic cysts of the pupillary margin.

Carbachol is a potent direct-acting miotic agent; its duration of action is longer than that of pilocarpine (8-10 hours) because of resistance to hydrolysis by cholinesterases. This drug also may act as a weak inhibitor of cholinesterase. Patients with an inadequate response to or intolerance of pilocarpine as a result of ocular irritation or allergy frequently do well on carbachol. The ocular and systemic adverse effects of carbachol are similar to but more frequent, constant, and severe than those of pilocarpine.[33] Clinical use of carbachol is limited.

Echothiophate is a cholinesterase inhibitor and is used in the treatment of POAG. It is a long-acting, relatively irreversible agent (limited commercial availability; see Table 114-4). This agent is a potent inhibitor of pseudocholinesterase, but also inhibits true cholinesterase. Because of the serious ocular and systemic toxic effects of echothiophate, it is reserved primarily for patients who are either not responding to or are intolerant of other therapy. Because of its cataractogenic properties, most ophthalmologists use this agent only for patients without lenses (aphakia) and for patients with artificial lenses (pseudophakia). The ocular and periocular parasympathomimetic adverse effects are more common and more severe than with pilocarpine or carbachol.

In addition to the parasympathomimetic effects, echothiophate may produce severe fibrinous iritis (particularly with the irreversible inhibitors), synechiae, iris cysts, conjunctival thickening, occlusion of the nasolacrimal ducts, and cataracts. The inhibition of systemic pseudocholinesterase by echothiophate decreases the rate of succinylcholine hydrolysis, resulting in prolonged muscle paralysis. Echothiophate should be discontinued at least 2 weeks before procedures in which succinylcholine is used.

The role of echothiophate in glaucoma is limited by its frequency and potential toxicity. For phakic patients, cholinesterase inhibitors should be administered only if intolerance or failure results with other antiglaucoma medications. Echothiophate provides additional IOP-lowering effects when used with β-blockers, CAIs, and sympathomimetic (adrenergic) agents. Only one concentration of this agent (0.125%) is currently available. A once-daily administration frequency should be used for most patients unless very high IOP is present.

The use of ELC likely improves response, reduces systemic adverse effects, and should be performed by all patients administering echothiophate. The drug should be used with caution for patients with asthma, retinal detachments, narrow angles, bradycardia, hypotension, heart failure, Down’s syndrome, epilepsy, Parkinsonism, peptic ulcer, and ocular inflammation, as well as in those receiving cholinesterase inhibitor therapy for myasthenia gravis or exposure to carbamate or organophosphate insecticides and pesticides.

Future Drug Therapies

It is hoped that new agents, improved formulations, and novel approaches to the reduction of IOP and other methods of prevention of glaucomatous visual field loss will provide more effective and better-tolerated therapies. Most areas of glaucoma development continue to focus on drugs that reduce IOP by either reducing aqueous production or increasing outflow. The efficacy and safety of omidenepag isopropyl (OMDI) 0.002%, a selective, nonprostaglandin, prostanoid EP2 receptor agonist, were evaluated in comparison with latanoprost 0.005% in participants with POAG or OHT. OMDI 0.002% was noninferior to latanoprost 0.005% in reducing IOP and was well tolerated.[7]

Classes of drugs in development include adenosine-1 receptor agonists, cannabinoids, serotonin agonists, dopamine agonists, nitric oxide/carbon dioxide modulators, and hydroxysteroid dehydrogenase inhibitors. Agents that are neuroprotective and act through mechanisms other than IOP reduction are also in development and are likely to be part of glaucoma therapy in the future.[24,52-54]

Development of new long-acting topical formulations (such as nanoparticulates), implants, ocular inserts, and drug-eluting punctal plugs may provide improved patient convenience and medication adherence in the future.[28]

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of drug therapy for the patient with glaucoma is to preserve visual function through reduction of IOP to a level at which no further optic nerve damage occurs. Because of the poor relationship between IOP and optic nerve damage, no specific target IOP exists. Indeed, drugs used to treat glaucoma may act in part to halt visual field loss through mechanisms separate from or in addition to IOP reduction, such as improvements in retinal or choroidal blood flow. Often a 25% to 30% reduction is desired, but greater reductions (40%-50%) may be desired for patients with initially high IOPs. For patients with glaucoma, an IOP of less than 21 mm Hg (2.8 kPa) generally is desired, with progressively lower target pressures needed for greater levels of glaucomatous damage. Even lower IOPs (possibly even below 10 mm Hg [1.3 kPa]) are required for patients with very advanced disease, those showing continued damage at higher IOPs, and those with normal-tension glaucoma and pretreatment pressures in the low-to-middle teens. The IOP considered acceptable for a patient is often a balance of desired IOP and acceptable treatment-related toxicity and of patient quality of life.

PATIENT EDUCATION

⑦ An important consideration for patients failing to respond to drug therapy is adherence. Poor adherence or nonadherence occurs in 25% to 60% of glaucoma patients.

A large percentage of patients also fail to use topical ophthalmic drugs correctly. Patients should be taught the following procedure:

1. Wash and dry the hands; shake the bottle if it contains a suspension.
2. With a forefinger, pull down the outer portion of the lower eyelid to form a “pocket” to receive the drop.
3. Grasp the dropper bottle between the thumb and fingers with the hand braced against the cheek or nose and the head held upward.
4. Place the dropper over the eye while looking at the tip of the bottle; then look up and place a single drop in the eye.
5. The lids should be closed (but not squeezed or rubbed) for 5 minutes after instillation. This increases the ocular availability of the drug and reduces systemic absorption.
6. Recap bottle and store as instructed.

Note that many patients are physically unable to administer their own eye drops without assistance. ELC also should be used to improve ocular bioavailability and reduce systemic absorption.[7] The patient induces ELC for 5 minutes by gently closing the eyes. ELC decreases nasolacrimal drainage of drug, thereby decreasing the amount of drug available for systemic absorption by the nasopharyngeal mucosa. The use of ELC may improve drug response significantly, reduce adverse effects, and allow less-frequent dosing intervals and the use of lower drug concentrations.

The use of more than one drop per dose increases costs, does not improve response significantly, and may increase adverse effects. When two drugs are to be administered, instillations should be separated by at least 5 minutes (preferably 10 minutes) to prevent the drug administered first from being washed out. The patient should be taught not to touch the dropper bottle tip with eye, hands, or any surface.

Adherence to glaucoma therapy usually is inadequate, and it always should be considered as a possible cause of drug therapy failure. Assessment of adherence by healthcare providers generally is poor; so all patients should be encouraged continually to administer prescribed therapy diligently as instructed. To improve adherence, the patient, family, and care providers should be fully informed of the expectations of therapy and the need to continue therapy despite a lack of symptoms. Possible adverse effects of the medication and ways to reduce them should be discussed. Adherence will be improved by good communication, simplified and well-tolerated dosing regimens, reminder devices, education, close monitoring, and individualized care planning.[7,43]

SELF-ASSESSMENT QUESTIONS

1. All the following are typical optic disc changes seen in primary open-angle glaucoma (POAG) *except*:

   A. Nerve fiber layer defects

   B. Cup-to-disc ratio of >0.5

   C. Splinter hemorrhages

   D. Papilledema

2. All the following are typical visual field findings in primary open-angle glaucoma (POAG) *except:*

   A. Enlargement of the blind spot

   B. General central field constriction

   C. Reduced contrast sensitivity

   D. Altered color vision

3. The following are typical symptoms of primary angle-closure glaucoma (PACG) *except*:

   A. Blurred or hazy vision with halos around lights

   B. Acute ocular pain or discomfort

   C. Nausea, vomiting, abdominal pain, and diaphoresis

   D. Double vision

4. Patients with primary open-angle glaucoma (POAG) or ocular hypertension (OHT) do not often exhibit which of the following signs?

   A. Optic disc abnormalities

   B. Cloudy cornea

   C. Elevated intraocular pressure

   D. Visual field loss

5. Which of the following is not normally considered a risk factor for OHT or POAG?

   A. Family history

   B. Black and Latino/Hispanic ethnicity

   C. Elevated intraocular pressure (IOP)

   D. Central corneal thickness greater than 555 microns

   E. Severe myopia

6. All of the following have been associated with drug-induced glaucoma in closed-angle glaucoma *except*:

   A. Topical anticholinergic agents

   B. Inhaled or topical glucocorticoids

   C. Miotic agents such as echothiophate

   D. Systemic antidepressants

7. Current recommendations for initiation of primary therapy for POAG may include all the following *except*:

   A. Timolol maleate

   B. Latanoprost

   C. Acetazolamide

   D. Brimonidine

   E. Dorzolamide

8. Recommendations for administration of systemic agent for acute angle-closure crisis would be which of the following?

   A. Timolol maleate

   B. Latanoprost

   C. Acetazolamide

   D. Brimonidine

   E. Dorzolamide

9. Which of the following is often considered the most reasonable initial therapy for POAG or OHT?

   A. Latanoprost

   B. Pilocarpine

C. Dorzolamide/timolol

D. Apraclonidine

E. Netarsudil

10. Which of the following agents would be most appropriate as adjunctive therapy for a patient currently treated with timolol for POAG?

A. Acetazolamide

B. Echothiophate

C. Betaxolol

D. Bimatoprost

11. Which of the following is not considered a reasonable treatment option in a patient with POAG?

A. Selective laser trabeculoplasty (SLT)

B. Trabeculectomy

C. Minimally invasive glaucoma devices (MIGS)

D. Peripheral iridectomy

12. Which of the following is *not* considered a reasonable treatment option for acute angle-closure crisis (AACC)?

A. Topical agents (eg, beta blockers, brimonidine)

B. Intravenous acetazolamide

C. Selective laser trabeculoplasty (SLT)

D. Intravenous mannitol

E. topical corticosteroids

13. All the following are ocular side effects related to prostaglandin analogs *except*:

A. Altered iris pigmentation or iris darkening

B. Miosis

C. Hypertrichosis or eyelash growth

D. Hyperemia

E. Loss of periorbital fat

14. Topical beta blockers have been associated with all of the following systemic side effects *except*:

A. Increased heart rate

B. Bronchospasm

C. Alteration of serum lipids

D. CNS effects

E. Reduced blood pressure

15. Eyelid closure (ELC) after ocular drug administration is an important technique that should be explained to all glaucoma patients for the following reasons *except*:

A. It is an easy technique for patients to learn.

B. It may improve ocular bioavailability.

C. It may reduce systemic absorption and thereby reduce some local and systemic adverse events associated with topical glaucoma therapy.

D. The patient is only required to gently close the eyes for 1 minute.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Papilledema is not exhibited in POAG (see Table 114-2).
2. **B.** General peripheral field constriction is prominent in POAG. Loss of central vision is more prominent in other ocular diseases (eg, Adult Macular Degeneration) (see Table 114-2).
3. **D.** Double vision would generally not be exhibited in most cases of PACG and only one eye is affected (see the "Clinical Presentation" box.)
4. **B.** A cloudy cornea is often exhibited in primary angle-closure glaucoma because of the acute IOP rise experienced in these patients. Patients with POAG or ocular hypertension (OHT) often do not exhibit highly elevated IOP and therefore their cornea often appear normal (see the "Clinical Presentation" Box).
5. **D.** Central corneal thickness that is less than 555 microns is considered for patients at greater risk for developing glaucoma. Thinner corneas may reflect a higher IOP than exhibited by tonometry (see the "Glaucoma Suspect and Ocular Hypertension" section).
6. **B.** Inhaled or topical corticosteroids often reduce aqueous humor outflow through the trabecular meshwork by accumulating extracellular material that block the outflow. The medication associated with PACG often causes acute changes in the lens/iris structures that allow for the angle to close and block aqueous outflow, thus resulting in an acute elevated IOP.
7. **C.** Acetazolamide for POAG is a systemic agent and not used in current practice to initiate therapy in a POAG patient (see the "Pharmacotherapeutic Approach" section).
8. **C.** Acetazolamide is the only systemic agent listed that is available for intravenous administration for an acute IOP elevation in a patient (see the "Acute Angle-Closure Crisis" section).
9. **A.** Latanoprost is the most commonly used agent, dosed once daily at bedtime. Pilocarpine is an older agent that has generally fallen out of use; apraclonidine does not have a primary indication and is seldom used except acutely; a combination product is not often considered initial therapy; netarsudil is a new product that has been considered adjunctive therapy (see the "Pharmacologic Agents Used in Glaucoma" section).
10. **D.** Echothiophate is considered a fourth-line agent with significant ocular side effects. Acetazolamide as an oral agent is not often considered for adjunctive therapy because of significant systemic side effects; betaxolol is another beta blocker and would not be used concurrently with timolol; bimatoprost is a PGA that would be most appropriate for additional IOP lowering benefit (see the "Pharmacologic Agents Used in Glaucoma" section).
11. **D.** A peripheral iridectomy is performed in a patient as a treatment for acute angle-closure glaucoma or as a preventive procedure for a patient at risk for AACC (see "Nonpharmacologic Therapy: Laser and Surgical Procedures" under section "Open-Angle Glaucoma").
12. **C.** SLT is a laser procedure used in POAG. A laser iridectomy is the procedure performed for AACC (see the "Acute Angle-Closure Crisis" section).

13. **B.** While PGAs may have an effect on iris pigmentation, they do not often exhibit any effect on iris constriction (miosis) (see the “Prostaglandin Analogs” section).

14. **A.** topical beta blockers are known to cause many of the same side effects seen with systemic beta blocker administration including bradycardia or decreased heart rate (see the “β-Blocking Drugs” section).

15. **D.** It is important for the patient to keep the eyelid closed for 5 minutes following ocular drug administration. One minute is not enough time to provide a benefit to the patient. Some have suggested 3 minutes may be enough time, but 5 minutes is the preferred time (see the “Patient Education” section).

Chapter 115: Age-Related Macular Degeneration

Alisa K. Escano; Casey S. Washington

KEY CONCEPTS

KEY CONCEPTS

① The hallmark sign of age-related macular degeneration (AMD) is the development of drusen in the macula. Drusen are yellow deposits of lipids between the retinal pigment epithelial and Bruch's membrane that can develop with age.

② AMD is identified as the leading cause of blindness in the industrialized world and a top cause of blindness worldwide.

③ The two most important risk factors for AMD are age and smoking.

④ The goal of treatment is to slow progression of AMD and prevent severe visual impairment or blindness.

⑤ Smoking cessation is the main modifiable risk factor that will slow progression of AMD. Pharmacists and other health professionals can play a vital role in helping people stop smoking.

⑥ Antioxidant vitamins and minerals may prevent cellular damage in the retina caused by the formation of free radicals through light absorption. Use may benefit patients the most with medium- or large-sized drusen and/or geographic atrophy in at least one eye.

⑦ For most patients with wet AMD and choroidal neovascularization, the use of intravitreal vascular endothelial growth factor (VEGF) inhibitors and other inhibitor-like drugs have led to improvement in visual acuity.

⑧ The appeal of the ranibizumab treat and extend (TREX) approach is the reduction of office visits and medication cost.

⑨ VEGF inhibitors and antioxidant vitamins and minerals are the only pharmacologic therapies available that have been shown to improve and stabilize visual acuity in patients with intermediate to advanced AMD.

Watch the first three age-related macular degeneration videos from the **National Eye Institute at** https://youtube.com/playlist?list=PLNol8zIT_P1Bjl8o7HNMCybk1tA3s0SlN. These short videos totaling 3 minutes provide a brief overview to age-related macular degeneration and animation of the pathophysiology. These videos are useful to enhance student understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

Age-related macular degeneration (AMD) is a neurodegenerative disease that produces irreversible loss of central vision due to damage to the macula, the center region of the retina. AMD is a leading cause of blindness due to age-related changes in the macula and, specifically, the photoreceptor–retinal pigment epithelial (RPE) complex.[2]

A general familiarity with the anatomy of the eye including the macula and photoreceptor–RPE complex will aid in understanding the disease and treatment mechanisms (Figs. 115-1 and 115-2).[3,4] The macula in the middle of the retina is responsible for all central vision, a significant part of color vision, and the fine detail images. The photoreceptor cells of the macula identify light and then transfer the information to the brain to produce an image. Central vision is needed to read, write, drive, watch television, and other typical activities of daily living. AMD reduces central vision, visual acuity, and blue-yellow color sensitivity leading to significant disability (Fig. 115-3).[5]

① The hallmark sign of AMD is the development of drusen in the macula. Drusen are yellow deposits of lipids between the RPE and Bruch's membrane that can develop with age (Fig. 115-4). Bruch's membrane is an extracellular layer separating the RPE from choroidal capillaries in the eye. Small drusen without additional abnormalities have a lower risk of progression to severe disease than large drusen.

FIGURE 115-4

Two distinct types of AMD have been identified: geographic atrophy (GA) "dry" and choroidal neovascularization (CNV), exudative "wet" (Fig. 115-5). Disease progression is unpredictable as visual disturbances do not correlate with drusen formation. Patients can monitor visual changes with an Amsler grid by using one eye at a time and looking for any distortions in the grid (Fig. 115-6).

The American Academy of Ophthalmology defines AMD by the presence of one of the following criteria[1]:

- Presence of at least intermediate-size drusen (63 µm or larger in diameter)

- RPE abnormalities (hypopigmentation or hyperpigmentation)
- Reticular pseudodrusen
- Presence of any of the following features: RPE GA, CNV, polypoidal choroidal vasculopathy, retinal angiomatous proliferation

EPIDEMIOLOGY

② With longer life expectancy, the incidence of vision impairment from macular diseases increased 62% from 1990 to 2010.[6] AMD is identified as the leading cause of vision impairment in the industrialized world and a top cause of blindness worldwide, in addition to diabetic retinopathy, glaucoma, cataracts, and under-correction of refraction error.[7–9] Drusen development and AMD diagnosis can occur at any age, although usually after the age of 50 years. The prevalence of AMD is 8.69% for adults 45 to 85 years of age.[10] Rates of AMD increase nonlinearly with age affecting 6% to 10% of people aged 65 years or older and more than 20% to 25% of who have reached the age of 75 years.[11,12]

Dry AMD is the most common type diagnosed in 80% to 90% of patients and 10% to 20% may progress to wet AMD.[7,11] The more severe wet AMD is associated with progressive vision loss and makes up only 10% to 20% of AMD diagnoses yet is responsible for 90% of the vision loss of AMD.[8]

In the United States, 2.8 million individuals have advanced or intermediate forms of AMD, with expectations to reach 5.44 million by 2050.[10,11] Cases of early AMD in the United States totaled 9.1 million in 2010 with expectations to increase to 17.8 million by 2050.[10]

Risk Factors

③ The two most important risk factors for AMD are older age and smoking. Additional risk factors for AMD include ethnicity and genetics, both of which are nonmodifiable. In addition to smoking, modifiable risk factors include hypertension, body-mass index (BMI), and cardiovascular disease (Table 115-1).[8]

TABLE 115-1

Risk Factors for AMD

Factor		Increased Risk	Protective
Age (years)	<55		✓
	55-75	✓	
	>75	✓	
Ethnicity	European	✓

Medications	Statins		✓

[a] Take into consideration race is a socially created categorization and not determinable by genetic testing.

[b] Gender nonbinary inclusive studies have not been performed; consult www.transhealth.ucsf.edu/guidelines.[34]

The risk of development of AMD increases exponentially with age, with risk at the age of 75 years 2 to 3 times that at 65 years. A 2014 worldwide meta-analysis found a higher prevalence of AMD in European compared to Asian, Hispanic, and African populations.[6,8] The Salisbury Eye Evaluation evaluated the prevalence of AMD of White and Black Americans and found higher prevalence of large drusen, focal hyperpigmentation, and GA in white participants, suggesting there may be a mechanism of protection against fundus abnormalities in the central zone for Black participants.[9]

Genetics

Several genetic factors are associated with increasing risk, progression, and protection from AMD.[8] The complement factor H (CFH)–related gene on chromosome 1 binds to factor C3b and is involved in regulation of the innate immune system. This regulation is defective with a homozygous Y402H polymorphism of *CFH*, causing alteration at the C3b site leading to an up-regulation of inflammation, affecting vascular endothelial growth factor (VEGF) expression, and increasing the risk of AMD by 7.4-fold.[13]

Other genetic variants associated with increased risk of AMD include the ARMS2/HtrA serine peptidase 1 (*HtrA1*) genes, hepatic lipase (*LIPC*) gene, and the rs3775291 variant in the toll-like receptor 3 (*TLR3*) gene.[8,13] Despite publications suggesting genetic testing may be helpful, genetic tests are not recommended in patient care at this time because of inconclusive data.[14,15]

Smoking

Because it is a modifiable risk factor, smoking is important for health professionals to address; it is associated with an increased risk of AMD.[8] Studies have consistently found an increased risk across different populations of early, wet, and dry AMD with current smoking and former smoking within the last 20 years.[8]

Smoking cessation is a staple in the care plan for patients at risk for and with a prior diagnosis of AMD due to the ability to slow progression. The Australian government added warnings to cigarette packs regarding the risk of blindness related to data from AMD.[16] In 2014, the United States Department of Health & Human Services published a report of the damage smoking can do to health; however, the warnings on cigarettes in the United States are opposed by the tobacco industry.[17,18]

Diet

Diets higher in saturated, transunsaturated, polyunsaturated, and monounsaturated fatty acids (FAs) are associated with higher prevalence and progression of AMD compared to diets with lower intake of fat.[8] Interestingly, FA in nuts and fish was protective. Omega-3 FA intake can decrease the risk of AMD by up to 30%.[8]

Antioxidant intake has also proven important in AMD.[19] Lutein, zeaxanthin, zinc, and vitamins C and E had varying results when evaluating supplements and dietary intake. Combining types of antioxidants, through a varied diet, tends to have better results.[20–22] A recent population-based cohort study found that patients who followed a diet consisting of 200 g of vegetables per day, fruit twice daily, and fish twice a week had a significantly reduced risk of AMD.[20] Dietary nitrate intake of 142 g/day, from vegetable and nonvegetable sources, was also found to reduce incidence of early AMD.[23]

Additional Risk Factors

AMD can loosely be linked to atherosclerosis and cardiovascular disease.[8,24] Risk factors of these disease states overlap, including hypertension, which is associated with a higher incidence of wet AMD. Obesity and inactivity are also associated with increased risk of early and late AMD.[25] 3-Hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are associated with a potential modest reduction in risk of early AMD and a protective effect against wet AMD; the drugs show no benefit or harm with respect to risk of dry AMD.[26] Aspirin was thought to increase the chance of developing wet AMD, but results have been conflicting and the minimal increase in the risk of wet AMD is less than the benefit in using aspirin for cardiovascular disease in older adults.[8,27]

Ultraviolet radiation exposure, especially in people with light-colored eyes, has also shown an increase in the risk of AMD.[28,29] Thyroid dysfunction and thyroxine use have both shown an association with increased AMD diagnosis.[30] Medications have also been associated with AMD including nitroglycerin, beta-blockers, chloroquine derivatives, and phenothiazines.[31] Environmental safety is a prudent component to evaluate due to unsafe chemicals and the need for a focus on sustainability in healthcare.[32] Pesticide exposure was correlated to AMD diagnosis in the Agriculture Health Study reporting that exposure to insecticides and herbicides is a modifiable risk factor for AMD.[33]

ETIOLOGY

AMD is a neurodegenerative disease with ocular inflammation and autoimmunity in combination with additional causes of RPE dysfunction and atrophy including the effects of aging, external environmental factors, and genetic factors.[8] Abnormal processing of complement, lipid, angiogenic, inflammatory, and extracellular matrix pathways contribute to the detrimental changes, but the pathogenesis of AMD is not fully understood. Oxidative stress and complement activation can increase RPE secretion of VEGF-A, which is associated with angiogenesis.

Wet AMD has CNV, which are new blood vessels created in the choroidal region of the eye. There are different types of wet AMD determined by how the CNV occurs and how it affects the RPE.[8] In type 1, formerly referred to as “occult,” CNV is categorized by lesions with leakage of blood or plasma proteins from immature choroidal blood vessels that remain below the RPE.[8] The extra volume may cause pigment epithelial detachment. Type 1 can progress to type 2. In type 2, often referred to as classic, lesions push through and are visible above the RPE. Type 3 has retinal angiomatous proliferation meaning the choroidal and retinal vessels link together. Retinal macrophages are increased and are a hallmark sign of CNV.[35]

Dry AMD has been labeled a metabolic storage disease, due to the excessive buildup of lipofuscin, a nondegradable debris that accumulates in the RPE with age or other toxic accumulations between the RPE and Bruch’s membrane.[36] The deposits on the semipermeable Bruch’s membrane interfere with efflux, increasing stress and inflammation on the RPE (Fig. 115-3). This stress, in addition to cigarette smoking and aging, increases lipofuscin that interferes with lipid metabolism. The extra volume shifts the original layers of the RPE complex resulting in GA.

Alzheimer’s disease, Parkinson’s disease, amyotrophic lateral sclerosis, and Huntington’s disease are other common neurodegenerative diseases of aging potentially related to AMD.

A reduction in quality of life (QOL) is common with AMD.[37] Clinical depression is reported in one-third of patients, twice the rate of peers without AMD, and this risk increases as vision deteriorates.[8,38] A significant decline in participation in valued activities such as hobbies can occur, which has been found to increase the risk of depression. Additionally, a meta-analysis reported an association of AMD, specifically late AMD, with an increased risk of all-cause and cardiovascular mortality.[39]

PATHOPHYSIOLOGY

The presence and type of drusen on the retina upon examination can predict the progression of AMD. Drusen are yellow-white deposits made up of protein and lipids that appear on a layer of the retina known as the Bruch’s membrane, a thin, semipermeable membrane that operates as a basement membrane for the retinal epithelium and mediates the metabolic exchange between the retina and the choroid (Fig. 115-3). While the exact cause of drusen is unknown, several hypotheses suggest that drusen are composed of lipids and cellular debris accumulation from the rods and cones of the retina that are not fully eliminated. While drusen are not a cause of or diagnostic of AMD, the presence of drusen on examination can increase a person’s risk of developing AMD. Patients younger than 50 years should consider hereditary factors for macular disease if signs and symptoms similar to AMD are present.[8]

Drusen can be classified as hard or soft (Fig. 115-4). Drusen that are small, round, well-defined spots located far away from one another on the retina are called “hard” drusen. Hard drusen are not a large cause for concern for vision loss or AMD as they may never progress to AMD or may be slow to progress. Most people over the age of 50 years have hard drusen present on their retina, and these are considered a natural consequence of aging. Soft drusen increase the risk for AMD (specifically wet AMD); these are larger drusen, are not well-defined with blurred edges, and are often clustered closer together on the retina. The presence of large, soft drusen is associated with vision loss and an increased risk for progression to AMD. Soft drusen can also lead to RPE detachment through the disruption of the retinal layers.

Dry AMD

Atrophic or dry AMD is a painless disease of the macula resulting in a gradual loss of vision. The most common form of AMD, dry AMD can progress slowly and is less threatening to central vision loss compared to wet AMD. Dry AMD is characterized by subretinal hard and soft drusen deposits, the thinning of the macula, RPE atrophy, and hyperpigmentation of the retina. The cause of dry AMD is unknown, but studies indicate that it may be related to inflammation, genetics, and environmental factors such as smoking and diet.[24,25]

Dry AMD is usually diagnosed in patients older than 50 years. As the eye ages, the macula begins to thin and break down. Early detection, self-care, and reduction of risk factors through better diet, smoking cessation, and vitamin supplementation can help to slow progression of the disease.

Dry AMD that progresses to the advanced stage—when there is progressive and irreversible loss of RPE, choriocapillaris, and photoreceptors leading to a loss of central vision—is called GA.[40] Severe GA can also progress to wet AMD.

Dry AMD usually affects both eyes, but in some patients, only one eye is affected. Patients with dry AMD in one eye may not have noticeable symptoms because the healthier eye will overcompensate for the eye affected by AMD. The patient's peripheral vision is not affected by dry AMD, so the vision loss may not be obvious in the early stages of the disease.

Symptoms of dry AMD are as follows[40]:

- Difficulty reading or driving (eg, increasing blurriness of written words)
- Visual distortion (eg, straight lines appearing bent)
- Blurred images (eg, difficulty recognizing faces)
- Difficulty seeing in low or dim light; bright light may be needed to see better
- Decreasing central vision
- Colors may not appear as bright as they once were

Wet AMD

CNV, or exudative AMD, is typically referred to as wet AMD and is advanced AMD.[8,41] Wet AMD is characterized by the loss of central vision caused by CNV, which is the abnormal growth of new blood vessels from the choroid into the macula and retina. These abnormal blood vessels can leak blood or fluid into the retina and can form pockets of fluid between the choroid and the RPE; these can be seen as bumps in the macula and cause a disruption in central vision. The patient will see dark spots (floaters) in their central vision because of the pockets of fluid and wavy lines instead of straight lines because their macula is no longer smooth. The presence of drusen that are large and soft and RPE hyperpigmentation increases the risk of the development of wet AMD.

VEGF plays an important role in the pathogenesis of wet AMD. VEGF is a specific and potent regulator of angiogenesis and is responsible for the abnormal growth of blood vessels. One isoform, VEGF-A, is most strongly associated with angiogenesis in ocular diseases and is therefore a target for VEGF inhibitors for the treatment of wet AMD.[8,42]

Like dry AMD, wet AMD may affect one or both eyes. Once the patient has progressed to wet AMD, vision loss may be rapid if treatment is not initiated promptly to address the leaky blood vessels. Symptoms of wet AMD are similar to dry AMD and also include the presence of dark spots in the patient's central vision; peripheral vision is not affected. Patients at high risk of wet AMD should have regular eye examinations to assess functional change.

Classification of AMD

AMD can be classified using different systems. Most practitioners use the Age-Related Eye Disease Study (AREDS) classification or the more recently developed Beckman Classification system (Table 115-2), which is based on the presence and size of drusen and pigmentary changes.[8,43]

TABLE 115-2

Classification of Age-Related Macular Degeneration

Clinical Classification	Characteristics
Normal aging changes	Small drusen ≤63 µm No pigmentary abnormalities
Early AMD	Medium-sized drusen >63 µm and ≤125 µm No pigmentary abnormalities
Intermediate AMD	Large drusen >125 µm and/or any pigmentary abnormalities
Late AMD	Neovascular AMD and/or GA
AREDS Classification	
No AMD (Category 1)	No or few small drusen
Early AMD (Category 2)	Multiple small drusen Few intermediate drusen Mild abnormalities in the retinal pigment epithelium
Intermediate AMD (Category 3)	Any of the following: ○ Numerous intermediate drusen ○ At least one large drusen ○ GA
Advanced AMD (Category 4)	One or more of the following: ○ GA of the retinal pigment epithelium involving the foveal center ○ Neovascular maculopathy that includes the following: ■ CNV ■ Serous and/or hemorrhagic detachment of the neurosensory retina or retinal pigment epithelium ■ Retinal hard exudates ■ Subretinal and subretinal pigment epithelium fibrovascular proliferation ■ Disciform scar (subretinal fibrosis)

AREDS, Age-Related Eye Disease Study; AMD, age-related macular degeneration.

Early AMD

AREDS defines early AMD based on the presence of a few small (<63 µm) to medium (63-124 µm) drusen. The patient may or may not have pigment epithelial abnormalities in the macula. Patients diagnosed with early AMD have a low risk of progressing to advanced AMD after 5 years of stable disease.[43]

Intermediate AMD

Intermediate AMD has been defined by the AREDS as having one or more large drusen (≥125 μm in diameter) or evidence of extensive medium drusen (63-124 μm) or in one or both eyes. Patients with intermediate AMD have a much greater chance of progression to advanced AMD if left untreated. If, at baseline diagnosis, drusen are present only in one eye, there is approximately an 18% chance that the disease will progress to advanced AMD after 5 years. If medium to large drusen are present in both eyes, the risk of progression to advanced AMD increases to 26% after 5 years.[43] Upon diagnosis, patients should begin a discussion with their physician about the risks and benefits of delayed progression or stabilized visual acuity with the available treatment options.

Reticular pseudodrusen, also called subretinal drusenoid deposits, may appear in patients with intermediate AMD. These are difficult to identify upon examination, and diagnosis may require the use of fundus autofluorescence, infrared reflectance, and/or spectral domain optical coherence tomography (SD-OCT). The presence of pseudodrusen is associated with the progression of intermediate AMD.[8,44–47]

Advanced AMD

AREDS defines advanced AMD as neovascular AMD or GA present in the macula. In patients with advanced AMD, at least one eye is affected, with a complete loss of visual acuity. According to AREDS, the risk of progression of visual acuity loss in the unaffected eye is 35% to 50% at 5 years.[48] Patients with GA may have a slower loss of visual acuity compared with patients with neovascular AMD.[8]

CLINICAL PRESENTATION

AMD can present without symptoms, or patients may have complaints of central vision loss, including scotoma (a dark patch in the middle of their vision), or distorted vision. Patients are typically older than 50 years. In dry AMD, patients may complain of the need for a bright light or a magnifying glass while reading or trouble seeing while driving. Wet AMD presents as metamorphopsia, the distortion of straight lines. Acute vision loss requires urgent evaluation and care.

CLINICAL PRESENTATION: Age-Related Macular Degeneration

Signs

- Distortion when viewing the Amsler grid (Fig. 115-6)
- Dilated eye examination with a slit-lamp instrument to observe and measure
  - Dry: drusen, GA present as hypopigmentation or hyperpigmentation
  - Wet: subretinal fluid or hemorrhage, which requires other diagnostic tests

Laboratory Tests

- None

Diagnosis Tests

- Subretinal evaluation using fluorescein dye retinal angiography, optical coherence tomography, or fundus autofluorescence

TREATMENT

④ The goal of treatment is to slow progression of AMD and prevent severe visual impairment or blindness. It should be noted that while pharmacotherapeutic options do exist, there is not enough supportive evidence to advocate for one treatment option over another to prevent progression to advanced AMD. For patients with intermediate AMD, studies support the use of antioxidant vitamins and minerals to slow progression to advanced AMD. In patients with wet AMD, the use of anti-VEGF agents, photodynamic therapy (PDT), and even surgery has been studied in an attempt to slow progression to vision loss. Assessment of the patient by the physician and informed discussion with the patient evaluating the risks and benefits of treatment are necessary before treatment begins.

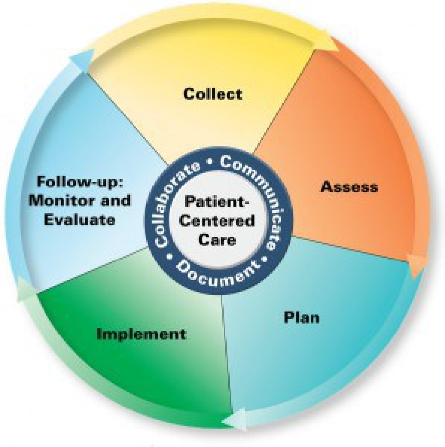
Smoking Cessation

⑤ For all patients with dry AMD, smoking cessation is crucial to include as the first-line nonpharmacotherapeutic treatment option. Smoking cessation is the primary modifiable risk factor that can slow progression of AMD.

Health professionals, particularly pharmacists, can play a vital role in providing patient counseling and assistance with choosing the appropriate over-the-counter (OTC) nicotine replacement therapy (NRT) options for patients. A Cochrane review evaluated evidence supporting the effectiveness of community pharmacists and their role in helping patients achieve smoking cessation. Well-trained, community pharmacists who provide behavioral counseling and education on choosing the appropriate NRT were able to help patients achieve smoking cessation goals. In the community setting, behavioral counseling and education for at least 1 month yielded positive smoking cessation rates.[40,49] Because most smoking cessation products in the United States are widely available OTC, community pharmacists have an opportunity to make a significant impact by helping a patient choose the appropriate NRT agent and dose while also providing the necessary counseling to support the patient (see Chapter 86, "Substance-Related Disorders: Alcohol, Nicotine, and Caffeine").

PATIENT CARE PROCESS

Patient Care Process for Management of Age-Related Macular Degeneration



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (age, sex, distance from treatment center, burden of follow-up visits, satisfaction, financial burden of treatment)
- Patient history (past medical, family history of AMD, social, smoking; date, frequency, and results of past eye examinations)
- Changes in vision (see Fig. 114-3 in the Glaucoma chapter and Fig. 115-5)
- Current medications

- Objective data (see the “Clinical Presentation” box)
- Visual field changes and losses
- Macula changes

Assess

- QOL
- Vision status (general, near, distance, peripheral)
- Mental health
- Smoking status
- Current treatment
- Functional status including driving, dependency, and role difficulties and activities of daily living (ADLs)

Plan

- Drug therapy regimen designed to prevent progression of the disease and preserve visual acuity, including specific agent(s), dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Table 115-4)
- Referral to an ophthalmologist as needed

Implement*

- Provide patient education regarding all elements of the treatment plan
- Provide education on diet and functional/lifestyle changes, adherence to medications, and use of the Amsler grid
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, usually 4 to 8 weeks, or as needed for specific medications

Follow-up: Monitor and Evaluate

- Monitor vision with Amsler grid (Fig. 115-6)
- Visual fields and diagnostic tests
- Adverse effects to medications
- Adherence to treatment
- Functional status
- Disease/treatment burden; financial burden

*Collaborate with patient, caregivers, and other healthcare professionals.

Antioxidant Vitamins and Minerals

⑥ Several studies looked at the benefit of antioxidant vitamins and minerals in slowing the progression of AMD.[43] These trials are based on the hypothesis that antioxidant vitamins and minerals may prevent cellular damage in the retina caused by the formation of free radicals through light absorption. Use may benefit patients the most with medium or large drusen and/or GA in at least one eye.

Patient-specific factors must be considered before recommending available antioxidant vitamins and minerals to patients with dry AMD (Table 115-3). AREDS evaluated the effects of high doses of vitamins E, C, and beta-carotene plus zinc (once-daily doses of vitamin E 400 IU, vitamin C 500 mg, beta carotene 15 mg, zinc 80 mg as zinc oxide, and copper 2 mg as cupric oxide) in patients with AMD with an average follow-up of 6.3 years. Compared with placebo, the supplements decreased the progression to visual acuity loss significantly in patients with intermediate and advanced disease in both the wet and dry forms of AMD. Patients with mild or borderline AMD did not demonstrate a benefit. The use of zinc alone in patients with AMD has significantly lowered the risk of progression to advanced AMD.[43]

TABLE 115-3

Selected[a] Commercially Available Vitamin Products Useful in Age-Related Macular Degeneration

Brand Names	Active Ingredients	Dosage Forms	Directions
AREDS Formulation			
Preservision AREDS	Vitamin E 400 IU, vitamin C 452 mg, beta carotene 28,640 IU, zinc 69.6 mg as zinc oxide, and copper 1.6 mg as cupric oxide	Softgel, tablet	**Softgels**: 1 softgel twice daily **Tablets**: 2 tablets twice daily
AREDS 2 Formulation			
Preservision AREDS 2	Vitamin E 400 IU, vitamin C 500 mg, zinc 80 mg as zinc oxide, and copper 2 mg as cupric oxide, lutein 10 mg, zeaxanthin 2 mg	Softgel, chewable	1 softgel twice daily
Miscellaneous formulations containing components of the AREDS and AREDS 2 ingredients			
Pro-Optic	Vitamin E 200 IU, vitamin C 500 mg, zinc 25 mg, copper 2 mg, lutein 10 mg, zeaxanthin 2 mg	Capsule	1 capsule daily
Equate Vision Formula with Lutein, Zexanthin & Omega-3 50+	Vitamin E 30 IU, vitamin C 150 mg, zinc 9 mg, copper 1 mg, omega-3 250 mg, lutein 5 mg, zexanthin 1 mg	Tablet, softgel	1 tablet/softgel daily with food
Equate Vision Formula with Lutein	Vitamin A 1,000 IU, vitamin C 200 mg, vitamin E 60 IU, zinc 40 mg, selenium 55 mcg, copper 2 mg, lutein 2 mg	Tablet	1 tablet daily
Visivite AREDS 2 Eye Vitamin	Vitamin C 500 mg, vitamin E 400 IU, zinc 40 mg as zinc oxide, copper 1 mg as copper oxide, lutein 10 mg, zeaxanthin 2 mg	Capsule	1 capsule twice daily with meals
ActiveEyes AREDS 2	Vitamin E 266 mg, vitamin C 500 mg, zinc 80 mg as zinc oxide, copper 2 mg as copper gluconate, lutein 10 mg, zeaxanthin 2 mg (per 2 capsules)	Capsule	1 capsule twice daily
EyePromise AREDS 2	Vitamin C 500 mg, vitamin D3 2,000 IU, vitamin E 400 IU, fish oil EE 250 mg, mixed	Softgel	1 softgel

	tocopherols 20 mg, alpha lipoic acid 10 mg, zeaxanthin 10 mg, lutein 10 mg		twice daily
Viteyes classic AREDS 2	Vitamin C 500 mg, vitamin E 400 IU, zinc 25 mg as zinc oxide, copper 1.2 mg as cupric oxide, lutein 10 mg, zeaxanthin 2 mg	Capsule	1 capsule twice daily with meals
Dr. Krawitz Eye Vitamins Macular Support	Vitamin E 100IU, vitamin C 500 mg, zinc 40 mg, copper 1 mg, lutein 15 mg, zeaxanthin 3 mg, calcium 115 mg, vitamin B6 20 mg, selenium 200 mcg, bilberry 50 mg, alpha lipoic acid 20 mg, grape seed extract 20 mg, L-gluthione 10 mg	Soy free, GMO free, gluten free, sugar free vegetarian capsule	2 capsules daily
MaxiVision Ocular Formula	Vitamin C 500 mg, vitamin D3 600 IU, vitamin E 400 IU, zinc 25 mg, copper 1.6 mg, lutein 20 mg, zeaxanthin 4 mg	Capsule	2 capsules per day during a meal
Systane I-Caps AREDS	Vitamin E 400 IU, vitamin C 425 mg, beta carotene 28,640 IU, zinc 69.6 mg, copper 1.6 mg	Softgel, coated tablet	1 tablet/softgel twice daily
Systane I-Caps AREDS 2	Vitamin E 400 IU, vitamin C 500 mg, zinc 25 mg, copper 2 mg, lutein 10 mg, zeaxanthin 2 mg	Softgel, chewable tablet	1 softgel/tablet twice daily
Ocuvite Eye Vitamin & Mineral supplement 50+	Vitamin E 20 mg, vitamin C 150 mg, zinc 9 mg, copper 1 mg, lutein 5 mg, zeaxanthin 1 mg, omega-3 fatty acids 250 mg	Softgel	1 softgel twice daily

[a] Not an all-inclusive list.

Previous studies have shown that the use of beta-carotene is associated with an increased risk of lung cancer in smokers, thus limiting its use in this population to nonsmokers only.[50] In the AREDS 2 study, beta-carotene was replaced with lutein 10 mg and zeaxanthin 2 mg; other components of the AREDS formulation of antioxidant vitamins and minerals remained the same. The replacement combination reduced the progression of AMD and therefore would be a reasonable substitute for beta-carotene in patients with AMD who smoke.[51]

The antioxidant property of saffron and its effect on visual acuity in AMD was studied in a small number of patients older than 50 years with mild-to-moderate AMD. Study participants received saffron 20 mg/day for 3 months and were followed for 6 months. Participants who received saffron and the antioxidant vitamin cocktail studied in the AREDS study demonstrated a modest improvement in visual function compared with placebo. Continued study of saffron in a larger sample of this patient population is needed to fully support its use in improving visual acuity in AMD.[52]

Specific Treatments for Wet AMD

Decisions about specific therapies for wet AMD must take into account the risks and benefits of the various therapies and the likelihood of visual recovery. Patients with smaller, more recent drusen are more likely to benefit from therapy. Therapies discussed below—VEGF inhibitors, PDT, and surgical therapy—are specific for wet AMD.

VEGF Inhibitors and Inhibitor-Like Drugs

⑦ For most patients with wet AMD and CNV, the use of intravitreal VEGF inhibitors and other inhibitor-like drugs has improved visual acuity and decreased blindness in about 50% of treated patients.[42] VEGF is a potent endothelial cell-specific mitogen and vascular permeability factor that is produced by many cells in the body including tumor cells, macrophages, and platelets.[8] As discussed earlier, VEGF-regulated CNV is a major cause of vision loss caused by the growth of new abnormal blood vessels through the Bruch membrane into the subretinal space. VEGF inhibitors play a pivotal role in preventing neovascularization in patients with wet AMD by preventing the growth of new blood vessels into the retina. Inhibition of VEGF in AMD can limit the progression of AMD and stabilize or reverse vision loss. Early initiation of VEGF inhibitors can have a significant effect on vision outcomes. Delay in therapy after early AMD symptoms have appeared has been associated with poor vision outcomes post-VEGF inhibitor initiation.[8]

Three recombinant humanized monoclonal antibodies—bevacizumab, ranibizumab, and brolucizumab-dbll—exert their mechanism of action as VEGF inhibitors. By acting as VEGF inhibitors in AMD, these monoclonal antibodies inhibit neovascularization within the retina by preventing the growth and leakage of new blood vessels into the retina, thus slowing the loss of vision.

Bevacizumab is a humanized monoclonal antibody approved by the US Food and Drug Administration (FDA) for ovarian, non-small-cell lung, glioblastoma, and colorectal cancers and is used off label intravitreally for wet AMD. It exerts its effect on all isoforms of VEGF. Compared with ranibizumab, bevacizumab is much less expensive.[53] Structurally, ranibizumab and bevacizumab are different but related monoclonal antibodies.

Ranibizumab is a fragmented monoclonal antibody that was genetically engineered to have an increased binding affinity for all biologically active forms of VEGF, allowing for increased VEGF inhibition. This is achieved by a modification of the amino acid sequence in ranibizumab.

Studies comparing the efficacy of bevacizumab to ranibizumab given monthly or as needed have found that both drugs improve visual acuity, with no significant differences seen in efficacy.[54,55] Both drugs also demonstrated similar safety data, with no differences seen in mortality, hospitalizations, or atherothrombotic events.

⑧ Ranibizumab has been studied for efficacy in increasing and maintaining visual acuity using a treat and extend (TREX) approach to dosing compared to the traditional monthly dosing (Table 115-4). The appeal of the ranibizumab TREX approach is the reduction of office visits and cost of the medication. Visual acuity was maintained with the TREX approach in patients with wet AMD following the initial monthly injections for 3 months, and costs associated with monthly office visits for treatment and ophthalmic examinations were decreased.[56] The TREX method in patients using ranibizumab is thus preferred over monthly injections.[55,56] Premedication prior to injection is not generally necessary with bevacizumab or ranibizumab.

TABLE 115-4

Medications Used in the Treatment of Age-Related Macular Degeneration

Medication	Brand Names	Usual Doses	Notes
Antioxidant Vitamins: described in Table 115-3			
Monoclonal Antibody VEGF inhibitors: inhibit neovascularization within the retina by preventing the growth and leakage of new blood vessels into the retina			
Bevacizumab	Avastin	Intravitreal: 1.25 mg monthly for 3 months, then may be given monthly or as needed based on monthly ophthalmic assessment	
Ranibizumab	Lucentis	Intravitreal: 0.5 mg once a month (approximately every 28 days) TREX dosing Frequency may be reduced (eg, 4-5 injections over 9 months) after the first 3 injections or may be reduced after the first 4 injections to once every 3 months if monthly injections are not feasible	A regimen averaging 4-5 doses over 9 months is expected to maintain visual acuity and an every 3-month dosing regimen has reportedly resulted in a ~5 letter (1 line) loss of visual acuity over 9 months, as compared to monthly dosing which may result in an additional ~1-2 letter gain.
Ranibizumab-nuna	Byooviz	Intravitreal: 0.5 mg once a month (approximately every 28 days) TREX dosing Frequency may be reduced (eg, 4-5 injections over 9 months) after the first 3 injections or may be reduced after the first 4 injections to once every 3 months if monthly injections are not feasible	A regimen averaging 4-5 doses over 9 months is expected to maintain visual acuity and an every 3-month dosing regimen has reportedly resulted in a ~5 letter (1 line) loss of visual acuity over 9 months, as compared to monthly dosing which may result in an additional ~1-2 letter gain.
Brolucizumab-dbll	Beovu	Intravitreal: 6 mg once per month (approximately every 25-31 days) for 3 months, followed by 6 mg once every 8 to 12 weeks.	
Nonmonoclonal antibody VEGF inhibitors			
Aflibercept	Eylea	Intravitreal: 2 mg once every 4 weeks for the first 12 weeks, followed by 2 mg once every 8 weeks	Some patients may require every 4-week dosing after the first 12 weeks
Pegaptanib[a]	Macugen	Intravitreal: 0.3 mg once every 6 weeks	Does not improve visual acuity in patients with new-onset wet AMD

[a] Pegaptanib is not currently available in the United States.

Brolucizumab-dbll is a humanized single-chain antibody fragment that inhibits the VEGFR-1 and VEGFR-2 receptors by binding to three major VEGF-A isoforms. It is the latest VEGF inhibitor to be approved by FDA. Two studies that established efficacy of brolucizumab-dbll compared the monoclonal antibody to aflibercept for 48 weeks. Both of the studies found brolucizumab-dbll noninferior to the control group with regard to improvement in visual acuity. Doses studied for brolucizumab-dbll were 3 mg and 6 mg given every 12 weeks following an 8-week loading dose phase. If the patient improved or remained stable, doses were continued at 12-week intervals for a total of 48 weeks; if the disease worsened, dosing intervals were reduced to every 8 weeks. The control group was administered aflibercept 2 mg every 8 weeks for the 48-week study period.[57]

In addition to being noninferior to aflibercept, brolucizumab-dbll 6 mg doses were able to maintain the dosing interval at 12 weeks in more than 50% of the study participants throughout the 48-week study period. Additionally, a statistically significant difference was observed in the decrease in visual acuity in patients treated with brolucizumab-dbll 6 mg compared to aflibercept 2 mg after week 16 of the treatment. Overall, the studies concluded that the brolucizumab-dbll treatment is noninferior to aflibercept with improving visual acuity as measured by the mean best-corrected visual acuity change from baseline.[57]

VEGF Inhibitor Biosimilars

Ranibizumab-nuna, the first biosimilar of ranibizumab, was approved by the FDA with indications of dry AMD, macular edema, and myopic CNV. Another biosimilar currently under investigation for approval is bevacizumab-vikg (ONS-5010). The indications being studied for bevacizumab-vikg are dry AMD, DME, and branch retinal vein occlusion.[58]

The VEGF inhibitor drugs aflibercept and pegaptanib are also administered intravitreally in wet AMD. These drugs are pharmacologically classified as VEGF inhibitors and are not monoclonal antibodies such as bevacizumab or ranibizumab. Aflibercept and pegaptanib are primarily used in patients who have an insufficient response in visual acuity improvement to ranibizumab and bevacizumab.

The first VEGF inhibitor approved by the FDA for use in wet AMD was pegaptanib. Pegaptanib was approved by the FDA in 2004. Randomized controlled trials at the time of approval demonstrated efficacy with the 0.3-mg dose injected into the vitreous every 6 weeks, but pegaptanib does not improve visual acuity in patients with new-onset wet AMD compared with other VEGF inhibitors.[8] For these reasons, it is rarely used in clinical practice and has been discontinued in the United States.

Aflibercept is a pan-VEGF-A and placental growth factor blocker that exerts its action in wet AMD by competing for binding with VEGF-A.[8] It was approved by the FDA in 2011.

Aflibercept is dosed by intravitreal injections of three monthly loading doses, followed by 2 mg injected intravitreally every 4 to 8 weeks. While some patients may require every 4-week injections, there was no additional efficacy noted in the clinical trials in doses administered every 4 weeks compared with every 8 weeks. Therefore, in patients receiving aflibercept 2 mg every 8 weeks, the benefit is improvement of visual acuity without the burden and risk of monthly intravitreal injections or monitoring.

Efficacy and safety tolerability are similar between the two VEGF inhibitors, with the advantage being that aflibercept had the potential for a reduced administration schedule at every 2 months and a reduced monthly cost compared with aflibercept. Overall, it is unknown if there is a standard optimal dosing schedule for VEGF inhibitors.

Adherence with these medications is imperative to maintain the visual acuity gains achieved.[59] If therapy is not continued, the gains can be lost. Counseling patients on the importance of adherence, risks of nonadherence, and options if cost is prohibitive are needed for the continued benefit of VEGF therapy.

Agents in the Pipeline

Faracimab is a new agent in development with a combined mechanism of action.[60] In addition to being a VEGF inhibitor targeting VEGF-A, faracimab also inhibits angiopoietin isoform 2 (Ang-2), which is a growth factor in the Ang-Tie pathway, a main pathway involved in angiogenesis.[61] Inhibition of Ang-2 can improve vascular permeability. Several multicenter phase 2 trials have demonstrated the efficacy of faracimab, providing a therapeutic option that may be administered less frequently than monthly ranizumab therapy and maybe more efficacious at improving visual acuity.[62–64]

An ocular implant device designed to provide continuous delivery of ranizumab has recently been approved for use in patients with dry AMD and who has received at least 2 doses of a VEGF inhibitor intravitrealy with an improved response to therapy. Once implanted, the device will deliver a continuous dose of ranizumab. One other advantage to this device is that it only requires refilling every 6 months in a physician's office in a manner similar to receiving a traditional intravitreal injection of ranizumab.[65]

Photodynamic Therapy for Wet AMD

PDT is initiated in patients with wet AMD who fail to demonstrate an improvement in visual acuity with the use of VEGF inhibitors alone. PDT for AMD is performed by the intravenous injection of a photosensitizing dye, verteporfin, followed by activation of the dye using a photo laser applied through the use of a specialized contact lens. A physician then shines a laser into the patient's eye, focused on a localized area. The laser activates the dye, causing the formation of a thromboembolism within the abnormal blood vessels below the macula. The thromboembolism seals off the abnormal blood vessels, preventing further leakage of the fluid into the retina that is causing difficulty in vision.

PDT may be used with or without VEGF inhibitors in patients whose visual acuity has worsened while on treatment with VEGF inhibitors alone.[8] When used at least once in combination with the VEGF inhibitors ranibizumab or bevacizumab, it can help improve and maintain visual acuity with continued VEGF inhibitor administration. Several randomized controlled trials with verteporfin and ranibizumab indicate that the combination therapy of VEGF inhibitors with PDT was more effective in improving and maintaining visual acuity and required fewer PDT treatments than with PDT alone, yet more studies are needed.[8,66]

A meta-analysis of randomized clinical trials comparing the combination therapy of bevacizumab and PDT to bevacizumab monotherapy concluded that patients treated with combination PDT + bevacizumab required significantly less injections of bevacizumab with similar effects on visual acuity improvement and ocular side effects compared to bevacizumab monotherapy.[67] Results have been conflicting with aflibercept plus PDT usage and changes in visual acuity. A randomized trial was unable to demonstrate benefit in combination over monotherapy alone due to insufficient patients meeting criteria for dual therapy.

Side effects of PDT are light sensitivity for several days following the procedure and pain in the eye. Patient counseling should include instructions on avoiding exposure to direct sunlight, wearing dark sunglasses and protective clothing when outside, and using OTC analgesics such as acetaminophen for pain. Patients may experience blurry vision that is temporary and will subside. However, worsening vision or increasing eye pain should be reported to a physician.

Surgical Therapy

Management of AMD using surgical techniques is varied and requires further investigation. Surgical therapy is usually reserved in patients with substantial macular hemorrhages that lack a response to VEGF inhibitor therapy.

The most effective surgery for these patients has been the removal of submacular hemorrhages following the administration of tissue plasminogen activator (tPa) into the retina.[68] Visual acuity improves following surgery; however, it declines over time without the continued use of a VEGF inhibitor to decrease CNV.

Thermal laser photocoagulation is a surgical procedure that involves the use of a thermal laser seal to stop the leakage of fluid from abnormal blood vessel growth under the macula. The heat from the laser seals the abnormal, leaky blood vessels, preventing further fluid leakage and subsequent loss of visual acuity. The negative aspect of this procedure is that it can also destroy surrounding healthy retinal tissue as it seals the leaky blood vessels. Because of this risk, thermal laser photocoagulation is not used to seal vessels located directly under the center of the macula. Thermal laser photocoagulation does not restore vision loss in advanced AMD and should be used as early as possible in therapy to help prevent progression of the disease. Because of these limitations, thermal laser photocoagulation is rarely used in clinical practice.

Antioxidant Vitamins, Beta Carotene, and Zinc

As discussed earlier, antioxidant vitamins and minerals may be useful in delaying progression to advanced AMD in patients with the presence of drusen. The choice of vitamin formulation should be considered based on the patient's history of smoking. Smokers with AMD should be counseled to use only the vitamin formulation that contains lutein and zeaxanthin, whereas nonsmokers can use the formulations containing either beta-carotene or lutein and zeaxanthin. Attention should be paid to amount of vitamin E the patient is consuming daily to avoid vitamin E overdose with the use of other multivitamin supplements.

Daily doses should consist of vitamin C 500 mg, vitamin E 400 IU, lutein 10 mg, zeaxanthin 2 mg, zinc oxide 80 mg, and copper (cupric oxide) 2 mg. Beta-carotene 15 mg may be used in lieu of lutein and zeaxanthin in nonsmokers.

Statin Therapy

The use of statins to prevent the onset of AMD and progression of early AMD to late AMD has been evaluated in several randomized placebo-controlled studies. Epidemiologic data suggest a link between patients with atherosclerotic disease and AMD, and the use of statins may exert a protective effect in patients with AMD.[26,69] The rationale is that drusen are composed of lipid deposits that accumulate within the retinal layers. The effects of statins on drusen are hypothesized to be through a number of different mechanisms. Through the serum lipid lowering, statins may alter the formation of lipid deposits on the Bruch’s membrane.[17] Statins may also exert a protective effect against atherosclerosis and AMD by preserving the vascular supply to the outer retina.[18] There may also be an intraocular anti-inflammatory effect through the inhibition of VEGF. In AMD, elevated levels of VEGF may play a role in the development of CNV. Finally, statins may interfere with secretion of metalloproteinases, which when released play a role in the rupture of lipid plaques and neovascular development.[19]

Several studies have examined the effect of statins on preventing or reducing progression of AMD to vision loss. Studies evaluating simvastatin indicated there may be a benefit in patients with early AMD; however, sample sizes were small in one study and in the largest study, 30% of patients were lost to follow-up.[17,20] In both studies, no benefit was observed in patients with advanced AMD to support statin therapy. In a small pilot study of patients with advanced AMD, intensive therapy with atorvastatin 80 mg daily indicated a possible regression in drusen size and vision improvement, but a larger study should be conducted to confirm these effects.[21]

Overall, statin therapy is not recommended for the treatment of patients with AMD alone, as results from larger studies would be needed to support use.[8] Statins may be used in AMD patients with other indications such as a diagnoses of atherosclerosis, coronary artery disease, or hyperlipidemia.

Prevention of AMD

Antioxidant vitamins and minerals have not been proven to prevent the onset of AMD in patients with risk factors such as drusen.[70] One trial indicated that there may be some benefit in the use of B vitamins in preventing the onset of AMD. The study compared folic acid 2.5 mg/day, pyridoxine 50 mg/day, and cyanocobalamin 1 mg/day to placebo in women with an increased risk of cardiovascular disease without AMD. After 7 years of follow-up, more women in the placebo group had evidence of AMD compared to the treatment group. Additional studies with larger patient populations are needed to confirm these results. However, it is promising that the use of B vitamins may be beneficial in reducing the risk of AMD in women with cardiovascular disease.[71]

Diets rich in the omega-3 fatty acids, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) found in fish and plant-based omega-3 FA, such as alpha-linolenic acid (ALA), may play a role in decreasing the progression to advanced AMD in patients with intermediate AMD, as seen in several subsets of studies.[8] However, there is insufficient evidence to say that dietary modification can prevent AMD formation.[8,72]

As previously discussed, smoking cessation is imperative (Table 115-1).

EVALUATION OF THERAPEUTIC OUTCOMES

The overall goal of therapy for macular degeneration is to prevent vision loss through slowing down progression of the disease and preserving visual acuity.

⑨ VEGF inhibitors and antioxidant vitamins and minerals are the only pharmacologic therapies available that have been shown to improve and stabilize visual acuity in patients with intermediate to advanced AMD. It is important to counsel the patient when discussing the treatment options that they are not curative and may only serve to improve visual acuity from baseline. Current pharmacologic therapy options will require repeated long-term administration to maintain visual acuity.

No pharmacologic therapy has been shown to prevent AMD in patients with high-risk factors for development. Studies are conflicting regarding the implementation of a diet high in omega-3 fatty acids such as EPA and DHA found in fish and plant-based omega 3 fatty acid supplements, such as ALA for prevention of AMD. More studies are needed to fully support this indication.

CONCLUSION

Age-related macular degeneration remains one of the leading causes of blindness globally. Its impact on the QOL of the aging adult can be tremendous. Early detection of this disease is the key to preserving visual acuity and allows early initiation of pharmacologic therapy to help stabilize and slow vision loss.

ABBREVIATIONS

ALA	alpha-linolenic acid
AMD	age-related macular degeneration
AREDS	Age-Related Eye Disease Study
CFH	complement factor H
CNV	choroidal neovascularization
DHA	docosahexaenoic acid
EPA	eicosapentaenoic acid
FA	fatty acid
FDA	Food and Drug Administration
GA	geographic atrophy
HtrA1	ARMS2/HtrA serine peptidase 1
LIPC	hepatic lipase
NRT	nicotine replacement therapy
OTC	over the counter
PDT	photodynamic therapy
QOL	quality of life
RPE	retinal pigment epithelium
TLR3	toll-like receptor 3
TREX	treat and extend
US	United States
VEGF	vascular endothelial growth factor

SELF-ASSESSMENT QUESTIONS

1. Which of the following describe the pathophysiology of dry AMD?

   A. Detachment of the RPE cells

   B. Choroidal neovascularization below the RPE

   C. Lipid deposits on Bruch's membrane

   D. Retinal angiomatous proliferation

2. At what age is AMD the most prevalent?

   A. >50

   B. <50

   C. >65

   D. >75

3. What is a common presenting sign of wet AMD?

   A. Metamorphopsia

   B. Difficulty reading

   C. Trouble driving

   D. Decreased peripheral vision

4. The presence of which sign of AMD indicates dry AMD?

   A. Choroidal neovascularization

   B. Increased VEGF-A

   C. Drusen

   D. RPE detachment

5. For patients at risk and diagnosed with AMD, what lifestyle modification can prevent the progression?

   A. Exercise

   B. Vegetarian lifestyle

   C. Multivitamin use

   D. Smoking cessation

6. Which type of drusen are concerning for the progression of AMD?

   A. Hard

   B. Soft

   C. Small

   D. Medium

7. What pathophysiologic change is a target for medication treatment for AMD?

   A. Angiogenesis

   B. Drusen formation

   C. Inflammation

   D. Thinning macula

8. The therapeutic goals in the treatment of macular degeneration are centered toward:

   A. Reversing the presence of hard, yellow drusen on the surface of the macula

   B. Encouraging choroidal neovascularization to maintain visual acuity

C. Maintaining visual acuity through preservation of central vision

D. Slowing the progression of the disease through the conversion of soft drusen to hard drusen

9. When considering treatment options for a patient with age-related macular degeneration (AMD), which factors about the patient are important to assess?

A. Type of AMD, smoking status, gender

B. Type of AMD, age, gender

C. Type of AMD, smoking status, presence of renal disease

D. Type of AMD, smoking status, presence of central vision

10. Identify the initial therapeutic options for age-related macular degeneration. MS is a 60-year-old male who was recently diagnosed with intermediate dry age-related macular degeneration (AMD) in both eyes. MS has a history of hyperlipidemia, hypertension, and type 2 diabetes. He is a current smoker at ½ ppd. Medications are atorvastatin 20 mg po daily, lisinopril 20 mg po daily, metformin 1,000 mg po BID, and sitagliptin 100 mg po daily. What should the physician prescribe MS as initial therapy for his dry AMD?

A. Discontinue the atorvastatin, start an AREDS multivitamin daily, and counsel him on smoking cessation to slow down progression of AMD.

B. Start an AREDS multivitamin daily, counsel him on smoking cessation, and begin treatment with bevacizumab intravitreally to slow down progression of AMD.

C. Start an AREDS 2 multivitamin daily, counsel him on smoking cessation, and continue atorvastatin to slow down progression of AMD.

D. Start an AREDS 2 multivitamin daily, counsel him on smoking cessation, and recommend photodynamic therapy to slow down progression of AMD.

11. A patient comes into the pharmacy and asks which vitamin they should take to prevent the diagnosis of AMD. What information do you share with the patient regarding prevention of AMD?

A. Vitamins play no role in prevention of AMD and should not be used.

B. Only the Preservision AREDS 2 can be used for prevention.

C. Specific antioxidants show some role for certain patients.

D. Any multivitamin that contains beta carotene can be used.

12. What expectations can a patient started on bevacizumab therapy have related to progression of AMD?

A. Improved visual acuity

B. Cure

C. No longer need reading glasses

D. Restoration of vision to prediagnosis

13. A patient is started on a multivitamin with antioxidants and ranibizumab TREX dosing. This patient is also enrolled in a smoking cessation program and currently using nicotine patches. What monitoring should occur?

A. Amsler grid

B. Liver function tests

C. Serum creatinine

D. Cholesterol

14. You are counseling a patient with wet AMD after a PDT session. This patient receives combination therapy of PDT with bevacizumab. She is 65 years old, has Type 2 diabetes and hypertension. She is obese and is a social smoker and drinker. What counseling can you provide to her?

    A. Expect improved visual acuity with combination therapy

    B. Weight loss will allow a greater visual acuity improvement

    C. Smoking cessation is the best step she can take

    D. Thermal laser photocoagulation is the next step

15. A patient explains that his insurance coverage has lapsed and he is unable to afford his medications. What options does he have to prevent progression of his disease?

    A. Consider TREX

    B. Take a break from therapy until coverage is found

    C. Reach out to manufacturers for patient assistant programs

    D. Use a multivitamin

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Debris accumulates on Bruch's membrane in dry AMD. See the "Pathophysiology" section of this chapter for more information.

2. **D.** The incidence of AMD increases nonlinearly with age with the highest percentage in patients >75 years of age. See the "Epidemiology" section of of this chapter for more information.

3. **A.** Line distortion is a common finding with wet AMD. See the "Clinical Presentation" box for more information.

4. **C.** Dry AMD is characterized by drusen development. See the "Pathophysiology" section of this chapter for more information.

5. **D.** Smoking cessation has shown an increased risk of 32% of diagnosis of AMD and is associated with the progression and diagnosis of all types of AMD. For more information, see the "Risk Factors" section of this chapter.

6. **B.** Hard drusen are considered a normal part of aging. Large and soft drusen are markers for progression of AMD. See the "Pathophysiology" section of this chapter for more information.

7. **A.** Angiogenesis is responsible for the abnormal growth of blood vessels and is targeted by VEGF inhibitor therapy. See the "Treatment" section of this chapter for more information.

8. **C.** The main goal of therapy for age-related macular degeneration is the prevention of central vision loss by slowing down the progression of the disease and preserving visual acuity. See the "Treatment" section of this chapter for more information.

9. **D.** The type of AMD, whether the patient is a smoker, and the degree of central vision loss will guide the provider in choosing the type of long-term therapy for the patient to preserve visual acuity. See the "Treatment" section of this chapter for more information.

10. **C.** The most important therapeutic recommendation for this dry AMD patient is smoking cessation. The patient should be counseled about the importance of smoking cessation to prevent dry AMD progression and preserve vision. The AREDS 2 multivitamin and antioxidant formula contains

lutein and zeaxanthin, which replaced beta carotene that has been found in other studies to be associated with an increased risk of lung cancer in smokers. The statin does not have any proven benefit in decreasing the formulation of drusen in a patient with macular degeneration; however, it is beneficial to this patient due to his current medical history of hyperlipidemia. See the "Treatment" section of this chapter for more information.

11. **C.** Vitamins have shown benefit for patients with intermediate- or large-sized drusen and GA in at least one eye. For more information, see the "Antioxidant Vitamins and Minerals" section of this chapter.

12. **A.** VEGF inhibitors have only shown preservation of improved and stabilized visual acuity in AMD. There is no cure for AMD. For more information see the "Evaluation of Therapeutic Outcomes" section of this chapter.

13. **A.** Ranibizumab is an intravitreal injection with expected outcomes of improved and maintained visual acuity measured by an Amsler grid. For more information, see the "Patient Care Process" and "Treatment" sections of this chapter.

14. **C.** Regardless of therapy chosen, smoking cessation is the best way to prevent progression and allow improvement in visual acuity. For more information see the "Treatment" section of this chapter.

15. **C.** Adherence is imperative for the treatment of AMD. Maintaining any visual acuity improvement requires adherence. See the "Treatment" section of this chapter for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 117: Acne Vulgaris

Debra Sibbald; Cathryn Sibbald

KEY CONCEPTS

KEY CONCEPTS

① Acne is a highly prevalent disorder affecting adolescents and adults, with a large psychosocial impact.

② The etiology of this complex disease originates from multiple causative and contributory factors, including genetics and environment. The diagnosis is based on the patient's history and clinical presentation.

③ Acne is a disease of the pilosebaceous unit. Elements of pathogenesis involve defects in epidermal keratinization, androgen secretion, sebaceous function, bacterial growth, inflammation, and immunity.

④ Acne vulgaris is a chronic disorder which cannot be "cured." Goals of treatment and prevention include control and alleviation of symptoms by reducing the number and severity of lesions, slowing progression, limiting disease duration and recurrence, prevention of long-term disfigurement associated with scarring and hyperpigmentation, and avoidance of psychologic suffering. Targeting goals may increase patient adherence to therapy.

⑤ The most critical target for treatment is the microcomedone. Minimizing or reversing follicular occlusion will arrest the pathogenic acne cascade and involve combining treatment measures to target all pathogenic elements.

⑥ Nondrug measures are aimed at long-term prevention and treatment. Patients should eliminate aggravating factors, maintain a balanced, low-glycemic load diet, and control stress. Cleanse twice daily with mild soap or soapless cleanser and use only oil-free cosmetics. Comedone extraction in approximately 10% of patients produces immediate cosmetic improvement. Shave infrequently as possible, using a sharp blade or electric razor.

⑦ First-, second-, and third-line therapies should be appropriate for the severity and staging of the clinical presentation and directed toward control and prevention.

⑧ Treatment regimens should be tapered over time, adjusting to response. Combine the smallest number of agents at the lowest possible dosages to ensure efficacy, safety, avoidance of resistance, and patient adherence.

⑨ Once control is achieved, maintenance regimens should be simplified to continue with some suppressive therapy. Therapy must be continued beyond 8 weeks: efficacy is assessed through comedonal and inflammatory lesion count, control or progression of severity, and management of associated anxiety or depression. Safety end points include monitoring for treatment adverse effects.

⑩ Motivate the patient to continue long-term therapy through empathic and informative counseling.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Acne” by Dr Sheilagh Maguiness, pediatric dermatologist, available on the Society for Pediatric Dermatology Website (https://tinyurl.com/saa9t4s). This 5-minute video provides a brief overview regarding information patients need to know about acne vulgaris. The video is useful to enhance student understanding regarding what information to provide to patients regarding causes of acne, triggers, cleansing, over-the-counter and prescription options, directions for use, and precautions. It gives a brief summary of take-home points useful to direct counseling.

INTRODUCTION

In this chapter, we review the latest developments in understanding acne vulgaris and its treatment. The contents provide an analysis of the physiology of the pilosebaceous unit; the epidemiology, etiology, and pathophysiology of acne; relevant treatment with nondrug measures; and comparisons of pharmacologic agents, including drugs of choice recommended in best-practice guidelines. Options include a variety of alternatives such as retinoids, antimicrobial agents, hormones, and light therapy. Formulation principles are discussed in relation to drug delivery. Patient assessment, general approaches to individualized therapy plans, and monitoring evaluation strategies are presented.

EPIDEMIOLOGY

① Acne vulgaris is a chronic disease and the most common one treated by dermatologists. There is a high degree of variability in prevalence, age of onset, distribution, severity, and age of resolution.

The lifetime prevalence of acne approaches 90%, with the highest incidence in adolescents; it affects 9.4% of the general population, with trends reflecting higher rates in urban areas compared to rural villages, although these rates are subject to selection and detection bias due to differential access to providers.[1]

The onset of acne vulgaris during puberty occurs at a younger chronologic age in girls than boys (12% age 25-58 vs 3% in males of the same age) and periodic premenstrual flares may continue until menopause. It is triggered in children by the initiation of androgen production by the adrenal glands and gonads, and it usually subsides after the end of growth. However, to some degree, most patients continue to have symptoms into their mid-twenties, and there is evidence that the duration of acne may last into middle age for most women, recorded in 54% of women and 40% of men older than 25 years of age.[2] In puberty, acne is often more severe in boys in about 15% of cases, which is 10-fold greater than in girls. Women often have more severe forms during adulthood. When untreated, acne usually lasts for several years until it spontaneously remits. After the disease has ended, scars and dyspigmentation are not uncommon permanent negative outcomes.

Genetic factors have been recognized; there is a high concordance among identical twins, and there is also a tendency toward severe acne in patients with a positive family history of acne.

There are believed to be no gender differences in acne prevalence. A systematic review included five studies, with a pooled odds ratio of 1.07 (95% CI 0.42-2.7, males with reference to females), suggesting only a slightly higher odds in males.[3]

An international group of epidemiologists, community medicine specialists, and anthropologists have questioned whether acne might be predominantly a disease of Western civilization.[4] They assert that since acne vulgaris is nearly universal in westernized societies (afflicting 79%-95% of the adolescent population), one causative factor might be the Western glycemic diet. While this hypothesis is based on the observation that primitive societies subsisting on traditional (low glycemic) diets have no acne, the theory awaits validation and acceptance by the dermatologic community.

ETIOLOGY

② Acne is a multifactorial disease. Genetic, racial, hormonal, dietary, and environmental factors have been implicated in its development. Its psychologic impact can be severe.

Four major etiologic factors are involved in the development of acne: increased sebum production, due to hormonal influences; alteration in the keratinization process and hyperproliferation of ductal epidermis; bacterial colonization of the duct with *Propionibacterium acnes*; and production of inflammation with release of inflammatory mediators in acne sites. These are reviewed in the “Pathophysiology” section later in this chapter.

The role of heredity in acne has not been clearly defined; however, there is a significant tendency toward more serious involvement if one or both parents had severe acne during their youth.

Environmental factors play a major role in determining the severity and extent of acne and may influence the choice of topical treatments. Heat and humidity may induce comedones; pressure or friction caused by protective devices such as helmets, shoulder pads, or pillows, and excessive scrubbing or washing can exacerbate existing acne by causing microcomedones to rupture. Pressure may cause acne lesions to form in patients who do not have acne vulgaris: this variant is called *mechanical acne*. Friction, wool, or other rough textured fabrics and occlusive clothing may also be mechanical irritants. Hair styles that are low on the forehead or neck may cause excessive sweating and occlusion, exacerbating acne. In most cases acne is worse in winter and improves during the summer, suggesting a salutary effect of sunlight. However, in some cases, exposure to sunlight worsens the disease.[5] Studies examining the relationship between tobacco smoking and acne show inconsistent results; however, dermatologists have begun to counsel people to quit tobacco smoking as a potential auxiliary treatment for acne.

The importance of psychologic factors in this prolonged and capricious condition has been repeatedly stressed. Two-thirds of affected teenagers wish that they could speak with their physician and healthcare provider about acne, but only one-third do. Emotions, such as intense anger and stress, can exacerbate acne, causing flares or increasing mechanical manipulation: picking, excoriating, or pinching lesions sometimes subconsciously or in sleep. This is probably the result of increased glucocorticoid secretion by the adrenal glands, which appears to potentiate the effects of androgens.[6]

Dietary influences Current investigations explore associations between dietary influences and acne. Under study are dietary influences as factors in acne development as well as potential treatment modalities. This follows the dismissal of overinterpreted 40-year-old, poorly designed studies that disavowed potential effects of dietary ingestions on acne.[7-9] Three primary influences on development include dairy and growth factors in milk; whey protein in milk; and hyperglycemic-load diets.

A series of studies have linked consumption of dairy products with acne.[10,11] Acne has been positively associated with the reported quantity of milk ingested, particularly skim milk.[12] The Nurses Health Retrospective Study examining diet during high school in 47,355 women found an association between acne and milk intake, suggesting natural hormonal components of milk and/or other bioactive molecules in milk could exacerbate acne.[13]

Lactoferrin is a whey milk protein with anti-inflammatory activity. Lactoferrin-enriched fermented milk ameliorated acne vulgaris, selectively decreasing triacylglycerols in skin surface lipids.[13] Lactoferrin administered as a dietary supplement twice daily in mild-to-moderate acne vulgaris led to an overall improvement in acne lesion counts in adolescents and young adults.[14]

A meta-analysis of observational studies examined association of dairy intake and acne in children, adolescents, and young adults. Any dairy product—including milk, yogurt, and cheese—was associated with an increased odds ratio for acne in individuals aged 7 to 30 years; however, studies were heterogeneous in design, making comparisons difficult.[15]

Other studies suggest a role for insulin-like growth factor (IGF), increased by ingestion of high glycemic loads.[16,17] The strongest evidence supports a high-glycemic-load (HGL) diet as a significant factor in acne. In a randomized controlled trial, patients who eliminated high glycemic index foods showed a significant reduction in acne. Those who consumed a low-glycemic-load diet compared with a conventional HGL diet had improvements of facial acne after 12 weeks. Accompanying changes in physical and endocrinologic parameters suggest that decreases in total energy intake, body weight, and indices of androgenicity and insulin resistance may also be associated with observed improvements in acne.[18] Another study reported an improvement in acne and insulin sensitivity in low-glycemic-load diets compared with controls, suggesting nutrition-related lifestyle factors play a role in acne etiology.[19] Independent effects of weight loss versus dietary intervention need to be isolated. In an Australian study, participants who consumed low-glycemic-load diets had no reported cases of acne.[12]

Other studies showed correlations between increases in the ratio of saturated to monounsaturated fatty acids, acne lesion counts, and increased sebum outflow, suggesting a possible role of desaturase enzymes in sebaceous lipogenesis and the clinical manifestation of acne. These require further investigation.[20]

Univariate and multivariate analyses were used to examine results of a 2015 French survey of individuals (age 15-24 years) reporting or not reporting acne with associated epidemiologic variables. Daily consumption of chocolate and sweets (odds ratio 2.38) and regular use of cannabis (odds ratio 2.88) was independently and highly associated with acne. Smoking tobacco (>10 cigarettes daily) was highly protective. Respective roles of sugar, lipids, and milk were not investigated.[21]

The role of dietary factors in the development or progression of acne vulgaris cannot be dismissed. The practical recommendations would be to avoid excess sugar and skim milk. Further studies are ongoing, including reviewing antioxidants from nutritional and topical sources and probiotics as potential acne-fighting agents.[12]

PATHOPHYSIOLOGY

③ The pathogenesis of acne includes hyperseborrhea, abnormal follicular keratinization, and *Propionibacterium acnes* proliferation in the pilosebaceous unit. Recent research has shed some new light on the involvement of the sebaceous gland, as well as on the pro-inflammatory activity of the cutaneous microbiome. Acne progresses through the following four major stages:

1. Increased sebum production by the sebaceous gland
2. *P. acnes* follicular colonization (and bacterial lipolysis of sebum triglycerides to free fatty acids)
3. Release of inflammatory mediators
4. Increased follicular keratinization

Improved understanding of acne development on a molecular level suggests that acne is a disease that involves both innate and adaptive immune systems and inflammatory events. Receptors that regulate sebaceous lipid metabolism work in concert with receptors regulating epidermal growth and differentiation. Acne can be considered as a model of immune-mediated chronic inflammatory skin disease: an innate immune response that is not able to control *P. acnes* followed by a Th1-mediated adaptive immune response that becomes self-maintaining independently from *P. acnes* itself.[22]

Acne usually begins in the prepubertal period, when the adrenal glands mature, and progresses as androgen production and sebaceous gland activity increase with gonad development. During puberty, alteration of the sebaceous lipid profile, called dysseborrhea, together with stress, irritation, cosmetics, and potential dietary factors lead to inflammation and formation of different types of acne lesions.[23]

As shown in Fig. 117-1, acne results from the development of an obstructed sebaceous follicle, called a *microcomedone*. Sebaceous glands increase their size and activity in response to circulating androgens. Most patients with acne do not overproduce androgens (with some exceptions); instead, they have sebaceous glands that are hyperresponsive to androgens.[24] Patients with acne have a significantly greater number of lobules per gland compared with unaffected individuals.

FIGURE 117-1

Cascade of the pathogenesis of acne. *(Reprinted, with permission, from Mills OH, Kligman AM. Comedogenicity of sunscreens: Experimental observations in rabbits. Arch Dermatol. 1982;18(6):417-419.)*

Sebum production is induced by different receptors expressed by the sebaceous gland. Involved are the histamine receptor (activated by histamines); the hormonal DHT receptor (activated by androgens); the neuromodulator receptor (mainly substance P); and corticotrophin-releasing hormone (CRH) receptor (mainly activated by stress); molecular research has identified three other receptors that are expressed by the sebocyte and control sebum production. Each of these newly identified receptors is activated by a dietary substance.[23]

The peroxisome proliferator-activated receptors are stimulated by free fatty acids and cholesterol, which act in concert with retinoid X receptors to regulate epidermal growth and differentiation as well as lipid metabolism.

The insulin-like growth factor (IGF)-1 receptor is stimulated by sugar to increase lipid formation, mediated by sterol response element binding proteins. The leptin receptor is stimulated by fat. Leptin is responsible for creating lipid droplets within the sebocyte and induces pro-inflammatory enzyme and cytokine (interleukin [IL]-6 and IL-8) secretion as well.[23]

The sebaceous gland also acts as an endocrine organ in response to changes in androgens and other hormones. Oxidized squalene can stimulate hyperproliferative behavior of keratinocytes, and lipoperoxides produce leukotriene B4, a powerful chemoattractant.[24] The composition of sebum is changed, with a reduction in linoleic acid. The growth of keratinocytes changes. The infrainfundibulum increases its keratinization of cells with hypercornification and development of the microcomedone, the primary lesion of both noninflammatory and inflammatory acne.[22] Cells adhere to each other in an expanding mass, which forms a dense keratinous plug. Androgen hormones could be a stimulus to pilosebaceous duct hypercornification. Sebum, produced in increasing amounts by the active gland, becomes trapped behind the keratin plug and solidifies, contributing to open or closed comedone formation.

Interleukin-1-α upregulation contributes to the development of comedones independently of colonization with *P. acnes*. A relative linoleic acid deficiency has also been described.[24]

A prominent role is played by the follicular colonization by *P. acnes*. *P. acnes* displays several activities which promote the development of acne lesions, including the promotion of follicular hyperkeratinization; the induction of sebogenesis; and the stimulation of an inflammatory response by the secretion of proinflammatory molecules and by the activation of innate immunity, followed by a *P. acnes*–specific adaptive immune response. In addition, *P. acnes*–independent inflammation mediated by androgens or by a neurogenic activation, followed by the secretion in the skin of proinflammatory neuropeptides, can occur in acne lesions.[22]

The pooling of sebum in the follicle provides ideal substrate conditions for proliferation of the anaerobic bacterium *P. acnes*, generating a T-cell response, which results in inflammation.[25] *P. acnes* produces a lipase that hydrolyzes sebum triglycerides into free fatty acids. These free fatty acids may trigger the changes that lead to an increase in keratinization and microcomedone formation.[26,27] This closed comedone, or whitehead, is the first clinically visible lesion of acne. It takes approximately 5 months to develop. The closed comedone is almost completely obstructed to drainage and has a tendency to rupture.[28-30]

As the plug extends to the upper canal and dilates its opening, an open comedone, or blackhead, is formed. Its dark color is not due to dirt but to either oxidized lipid and melanin or to the impacted mass of horny cells. The cylindrically shaped, open comedone is very stable and may persist for a long time as soluble substances and liquid sebum escape more easily. Acne that is characterized by open and closed comedones is termed *noninflammatory acne*.

Acne produces chemotactic factors and promotes the synthesis of tumor factor-α and interleukin-1β. Cytokine induction by *P. acnes* occurs. Both recruitment of polymorphs into the follicle during the inflammatory process and release of *P. acnes*–generated chemokines lead to pus formation. The pus eventually bursts on the surface with resolution of the inflammation or into the dermis. *P. acnes* also produces enzymes that increase the permeability of the follicular wall, causing it to rupture, releasing keratin, hair, and lipids and irritating free fatty acids into the dermis. Several different types of inflammatory lesions may form, including pustules, nodules, and cysts and may lead to scarring.

Postinflammatory hyperpigmentation (PIH) and scarring are two sequelae of acne. A time delay of up to 3 years between acne onset and adequate treatment correlates to degree of scarring and emphasizes the need for early therapy.[7,8]

CLINICAL PRESENTATION

To correctly diagnose acne vulgaris, the clinician considers patient assessment, which includes distinguishing all the presenting signs and symptoms of the clinical presentation, reviewing diagnostic and assessment considerations (see Clinical Presentation box), as well as considering psychosocial issues, differential diagnosis, and the possibility of drug-induced acne.

CLINICAL PRESENTATION: Acne Vulgaris

Lesion Type: Acne Vulgaris Can Be Noninflammatory or Inflammatory

- Noninflammatory acne is characterized by open and closed comedones that develop from the subclinical microcomedo
- The closed comedo is visible as a 1 to 2 mm whitehead most easily seen when the skin is stretched. It is often inconspicuous with no visible follicular opening
  - Is the first clinical sign of acne
  - Has a tendency to rupture
- The open comedo or blackhead is large, approximately 2 to 5 mm, and dark-topped with contents extruding
  - is relatively stable
- Inflammatory acne is traditionally characterized as having papulopustular and/or nodular lesions, which may arise from the microcomedo or from noninflammatory clinically apparent lesions
- A pustule is formed from a superficial aggregation of neutrophils.
  - Appears as a raised white lesion filled with pus, usually less than 5 mm in diameter
  - Superficial pustules usually resolve within a few days without scarring
- A nodule is produced through deeper, dermal, inflammatory infiltration

    - Is the most severe variant of acne
    - Appears as warm, tender, firm lesions, with a diameter of 5 mm or greater
    - May be suppurative or hemorrhagic within the dermis, may involve adjacent follicles and sometimes extend down to fat
- Cysts are suppurative nodules named because they resemble inflamed epidermal cysts
    - Cystic acne may show double comedones, resulting from prior inflammation and fistulous links between neighboring sebaceous units
- Progression of inflammatory lesions
    - Pustules and cysts often rupture spontaneously and drain a purulent or bloody but odorless discharge[31]
    - Inflammatory lesions may itch as they erupt and can be tender or painful. Nodules may develop exudative sinus tracts resulting in tissue destruction
    - Often resolution of these lesions leaves erythematous or pigmented macules that can persist for months or longer, especially in dark-skinned individuals
- Nodules and deep lesions may result in scarring

Regions of Involvement

- Acne lesions can occur anywhere on the body apart from the palms and soles
    - Are usually located on the face, back, neck, shoulders, and chest
    - May extend to buttocks or extremities
    - One or more anatomic areas may be involved in any given patient
    - The pattern of involvement, once present, tends to remain constant
    - Comedones frequently have a midfacial distribution in childhood and, when evident early, are indicative of a poor prognosis
    - Skin, scalp, and hair are frequently oily

Severity Grading Taxonomies

US Food and Drug Administration (FDA) Investigator Global Assessment 2005[31]

Type 1	Almost clear: rare noninflammatory lesions with no more than 1 small IL
Type 2	Mild, some noninflammatory lesions, no more than a few inflammatory lesions (papules/pustules only, no nodules)
Type 3	Moderate: many noninflammatory lesions, some inflammatory lesions, no more than one nodule
Type 4	Severe: up to many noninflammatory and inflammatory lesions, but no more than a few nodular lesions

European Union Guidelines Clinical Classification[32,33]

I	Comedonal acne
II	Mild-to-moderate papulopustular (MMPP) acne
III	Severe papulopustular acne, moderate nodular acne (*this level combines FDA types 3 and 4, above*)
IV	Severe nodular acne, conglobate acne (*this is an additional level beyond the FDA types above*)

Diagnostic and Assessment Considerations

Palliating factors	Sunlight
Provoking factors	Premenstrual flares, humid environments, excessive sweating; exposure to chemicals; occlusive clothing; friction; oily cosmetics; manual manipulation; stress; diet (high glycemic load, dairy)
Associated symptoms	Itch, pain, fever
Medical conditions	May contribute to or coexist with acne, including endocrine factors (eg, irregular menses, hirsutism, alopecia), pregnancy, atopy
Allergies	May cause acne symptoms, or present a contraindication to therapy
Medication history	Products may cause or interact with acne signs and symptoms
Social habits	Diet or smoking
Family history	Genetic predisposition to acne
Psychosocial issues	Assess global and disease-specific quality of life (QOL) indicators or health-state utilities

Psychosocial Issues

Acne causes profound negative psychological and social effects on the quality of life (QOL) of patients. Assessment of acne's impact on QOL is an important consideration in clinical decision-making. The negative impact of facial acne is one of the primary motivators for patients to seek and to adhere to treatment.[34] The European Dermatology Forum S3-Guideline for the Treatment of Acne recommended adopting a QOL measure as an integral part of acne management.[35] Specific QOL indicators represent patients' perceptions of and reactions to their health. Assessing QOL impairment in patients with acne may aid in management by evaluating psychologic impact, which may not correlate with clinical severity; aid in detection of depression or need for psychologic care; and improve therapeutic outcomes.

Acne adversely affects all aspects of QOL. In addition to documentation regarding acne-specific QOL impairment, acne impact on general health and psychologic status has been assessed for relationship between sociodemographic variables, disease severity, and mental status on QOL of acne sufferers. In a report of 195 cases, acne impact on health status was worse compared to other chronic diseases. Authors concluded acne is not a minor disease in comparison with other chronic conditions. Age of onset is capable to influence general health quality (GHQ status), which in turn affects QOL.[36] Patients with acne experience functioning and emotional effects from their skin disease comparable with those experienced by patients with psoriasis, and patients with severe acne reported levels of social, psychological, and emotional problems as great as those reported by patients with chronic disabling asthma, epilepsy, diabetes, back pain, or arthritis.[35]

The European Academy of Dermatology and Venereology Task Force on QOL and Patient Oriented Outcomes and the Task Force on Acne, Rosacea and Hidradenitis Suppurativa have documented the QOL instruments that have been used in acne patients, with information on validation, purposes of their usage, description of common limitations and mistakes in their usage, and overall recommendations.[35]

There are many global scales that have been used to evaluate acne. Some include the World Health Organization Quality of Life (WHOQOL), Skindex,[37] the Dermatology QOL Index,[38] and the Children's Dermatology Life Quality Index (CDLQI). Examples of acne-specific scales include the Acne-specific QOL questionnaire,[39] the Acne QOL Scale,[40] the Acne Disability Index (ADI), and the Cardiff Acne Disability Index (CADI).[35] The Acne QOL Scale was developed to measure the impact of facial acne across four domains (acne symptoms, role-emotional, self-perception, and role-social) of health-related QOL. Health-state utilities (such as time trade-off [TTO]) are quantitative measures of patient preferences of health outcomes ranging from 0 (death) to 1 (perfect health) and can be used in clinical trials as outcome measures of treatment effects. TTO utilities for acne in the range of 0.94 to 0.96 can be compared with those of other diseases (eg, 0.92 for epilepsy, 0.94 for myopia), and help to identify the impact of acne on self-perception and psychologic functioning.[41]

Differential Diagnosis

Acne vulgaris is rarely misdiagnosed. The conditions most commonly mistaken for acne vulgaris include rosacea, perioral dermatitis, gram-negative folliculitis, and drug-induced acne.[42]

Acne rosacea (adult acne) is a chronic, progressive relapsing condition occurring after age of 30 years in fair-complexioned persons. The diagnosis is clinical and based on history and physical findings. There are four subtypes: erythematotelangiectatic changes (erythema, flushing, telangiectasia [spider veins], stinging and burning); progressing to papular-pustular changes (inflammatory lesions, with edema, papules, and pustules on central facial areas such as nose, cheeks, chin, and forehead); phymatous changes (thickened skin and prominent pores on nose, ears, chin, and eyelids; and ocular changes (foreign body sensation, dryness, burning, eyelid erythema).

Rosacea has key differences from acne vulgaris. Onset is not linked to androgens or endocrine changes; and comedones are not usually present. Aggravating factors include endogenous triggers: ingestion of alcohol, spicy foods, or hot drinks (especially those containing caffeine), smoking; and exogenous triggers: overexposure to sunlight; exposure to temperature extremes, heat and humidity, friction, irritating cosmetics, and steroids. Treatment may include antibiotics, particularly doxycycline (low, anti-inflammatory dose) or erythromycin, topical metronidazole, pimecrolimus or azelaic acid as well as agents to reduce erythema (alpha adrenergics).[43]

Perioral dermatitis occurs primarily in young women and adolescents and is characterized by erythema, scaling, and papulopustular lesions commonly clustered around the nasolabial folds, mouth, and chin. The cause is unknown.[44]

Gram-negative folliculitis (*Proteus, Pseudomonas, Klebsiella*) may complicate acne, with a sudden change to pustules or large inflammatory cysts occurring after long-term treatment of acne with oral antibiotics. Folliculitis may be caused by staphylococci. There is a sudden onset of superficial pustules around the nose, chin, and cheeks. Patients with suspected folliculitis should be referred.[45]

Several conditions include acne vulgaris as a characteristic component, and understanding the mechanisms involved in these syndromes provides insight into the pathogenesis of acne. These include polycystic ovary syndrome (elevated androgen levels); PAPA syndrome (pyogenic arthritis, pyoderma gangrenosum, acne; early onset arthritis with increased inflammatory activity), and SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis syndrome; sterile inflammatory arthro-osteitis, with *P. acnes* as a possible trigger).[25]

Drug-Induced Acne

In addition to the conditions induced by drugs that are presented in Chapter e121, "Drug-Induced Dermatologic Disorders," acneiform eruptions can also be caused by medications. Drug-induced acne is monomorphic, either comedonal with some inflammation or papular–pustular. Drugs most commonly implicated in inducing comedonal/inflammatory acne include those with hormonal effects (steroids, OCP), halogens (iodide, bromide), vitamins (B_2, B_6, B_{12}), tuberculostatic drugs (isoniazid, ethambutol), lithium salts, antiepileptics (phenytoin), cyclosporine, and azathioprine. Drugs that most commonly induce papular–pustular reactions include anti-inflammatory medications (NSAIDs), sulfamethoxazole–trimethoprim, cephalosporins, and diltiazem.

Systemic corticosteroids can cause a pustular inflammatory form of acne, especially on the trunk. Onset is abrupt at 2 to 6 weeks after initiation of therapy. Acne has also been associated with most of the potent topical steroids, but not with hydrocortisone, which lacks the ability to inhibit protein synthesis. Discontinuation of the steroid results in an initial worsening of appearance due to removal of the anti-inflammatory action of the steroid itself. Caution patients about this reaction, which can be subdued through judicious use of topical hydrocortisone.[44-47]

Antiepileptics and tuberculostatics are the most commonly implicated in drug-induced acne, followed by lithium. Other heavy metals inducing acne include cobalt (in vitamin B_{12}).[48] Halogens, especially an excess of iodide in seafood, salt, and health foods, can exacerbate acne. In addition, halogens can provoke de novo acne lesions in individuals who have increased external exposure often due to occupational contact, or pool or hot tub disinfection; this variant is called *chloracne*.

In addition, certain minor ingredients in cosmetics have been implicated in cosmetic acne, including isopropyl myristate, cocoa butter, and fatty acids.

TREATMENT

The first step in determining a safe and efficacious treatment regimen for acne vulgaris is to establish desired outcomes for the patient, regarding both short- and long-term goals.

Desired Outcomes (Goals of Treatment)

④ Acne vulgaris is treated as a chronic disease, as it demonstrates typical chronicity characteristics: manifests as either acute outbreaks or slow onset; patterns of recurrence or relapse; a prolonged course; and psychologic and social impact. There are two governing principles: the chronic nature warrants early and aggressive treatment, and maintenance therapy is often needed for optimal outcomes.

Acne requires long-term control. This must be stressed with the patient to encourage adherence to lengthy treatment regimens, which address management of current symptoms and signs and preventive measures.

Basic goals of treatment include alleviation of symptoms by reducing the number and severity of lesions (objective and subjective grading) and improving appearance, slowing progression, limiting duration and recurrence, prevention of long-term disfigurement associated with scarring and hyperpigmentation, and avoidance of psychologic suffering.

A significant percentage change in lesion counts is desirable: most patients empirically validate a margin of 10% to 15% reduction in facial lesion counts as appropriate. Patient global self-assessment of acne improvement is a primary outcome.

General Approach to Treatment

⑤ The most critical treatment target is the microcomedone. Eliminating follicular occlusion will arrest the whole acne cascade. Nondrug and pharmacologic treatment and preventive measures should be directed toward cleansing, reducing triggers, and combination therapy targeting all four pathogenic mechanisms. Combination therapy is often more effective than single therapy and may decrease side effects and minimize resistance or tolerance to individual treatments.

The approach to acne management is largely determined by:

1. Severity index
2. Lesion type: predominantly noninflammatory or inflammatory

3. Treatment preferences including patient choices
4. Cost implications
5. Skin type and/or ethnic group
6. Patient age
7. Adherence
8. Response to previous therapy
9. Presence of scarring
10. Psychologic effects
11. Family history of persistent acne

Topical therapy is the standard of care for mild-to-moderate acne. Those with moderate-to-severe acne will require systemic therapy.

Topical treatments work only where applied. To reduce new lesion development, they must be applied to the entire affected area rather than individual spots. Most cause initial skin irritation, which may result in nonadherence or discontinuation. Irritation can be minimized by starting with lower strengths and gradually increasing frequency or dose. Where irritation persists, changing formulation from alcoholic solutions to washes, gels, or more moisturizing creams or lotions might help.

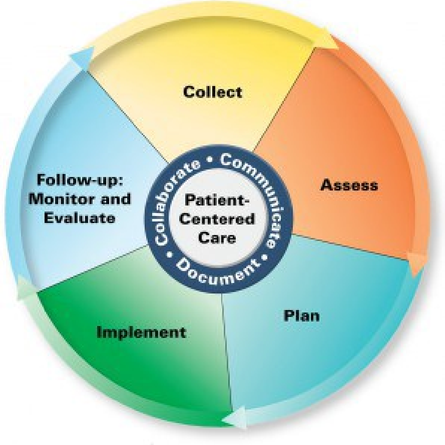
⑥ ⑦ First-line, second-line, and third-line therapies should be selected and altered as appropriate for the severity and staging of the clinical presentation. Treatment is directed at control, not cure. Regimens should be tapered over time, adjusting to response. Combine the smallest number of agents at the lowest possible dosages to ensure efficacy, safety, avoidance of resistance, and patient adherence. Once control is achieved, simplify the regimen but continue with some suppressive therapy. As it takes 8 weeks for a microcomedone to mature, therapy must be continued beyond this duration to assess efficacy. With the exception of topical antibiotics, most topical preparations may be used for years as needed.

Lesions typically recur for years. Microcomedones significantly decrease during therapy but rebound almost immediately after therapy is discontinued. The strategy for treating acne includes an induction phase followed by a maintenance phase, further supported by adjunctive treatments and/or cosmetic routines. Routine maintenance therapy involves regular use of appropriate agents to ensure remission and reduce potential for recurrence of visible lesions.

For successful long-term treatment, maintenance therapy must be tolerable, appropriate for the patient's lifestyle and convenience, continuing months to years, depending on age. Education about pathophysiology of acne and the psychosocial benefits of clearer skin are compelling reasons for patient adherence to consistent therapy to sustain remission.

PATIENT CARE PROCESS

Patient Care Process for Acne Vulgaris



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, race, sex, weight [body mass index], pregnant)
- Patient medical history (personal and family history, especially of acne or scarring, adrenal abnormalities)
- Social history (eg, psychosocial issues) and dietary habits including intake of glycemic foods, dairy, and sugary drinks (see Clinical Presentation/Diagnostic and Assessment Considerations; also section "Etiology")
- Current medications including OTC drug and nondrug measures, prescription drugs (eg, contraceptives) sunscreens, herbal products, dietary supplements, and prior acne medication use
- Current cosmetic use, including makeup, coverups, and cleansers
- Current use of devices (eg, comedone extractors)
- Inhaled systemic or contact allergies to drugs, cosmetics, foods, vehicle ingredients or excipients
- Objective data
  - Fitzpatrick phototype
  - Labs if relevant to monitoring for hepatic or renal function

Assess

- Presence of provoking factors or contributing factors (see Clinical Presentation/Diagnostic and Assessment Considerations) (eg, hormonal or adrenal anomalies: presence of vellus hair on females; in children: early age of onset [age 1-7 years], body odor, hair in axillary and pubic areas; and adrenal: rapid growth in children)
- Severity: number, type, and region of lesions; presence of scarring
- Hyperpigmentation of healed lesions (postinflammatory hyperpigmentation)
- Ability/willingness to adhere to long-term therapy
- Emotional status (eg, presence of anxiety, depression)

Plan*

- Goals: clear existing and prevent new lesions; reduce scarring, hyperpigmentation, and psychological impact
- Discontinuation of provoking habits, botanicals, or drug or nondrug measures
- Cleansing routine
- Drug therapy regimen including dietary, nonpharmacologic, and pharmacologic approaches
- Monitoring parameters including efficacy (eg, improvement or resolution of lesions and time frame) and safety (eg, sign and symptoms worsening, irritation, or allergy); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug-specific information, medication administration, or application technique)
- Self-monitoring for resolution of acne symptoms, occurrence of scarring, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, behavioral health, dietitian)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, adherence assessment

Follow-up: Monitor and Evaluate

- Improvement or resolution of acne symptoms (eg, noninflammatory or inflammatory lesions)
- Prevention of complications (eg, scarring, infection)
- Slow progression
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate duration of therapy every 3 months

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

Nonpharmacologic Therapy

⑧ ⑨ Encourage patients with acne to discontinue or avoid aggravating factors, including occlusion from mechanical factors or cosmetics, maintain a balanced, low-glycemic-load diet, and control stress. By being empathic and informative during counseling, the health professional may motivate the patient to continue long-term therapy.[1,4,43] One of the first approaches to nondrug management of acne is attention to cleansing techniques. Shaving recommendations, comedone extraction, dietary considerations, issues relating to ultraviolet light, and prevention of cosmetic acne should be reviewed with patients.

Cleansing

A systematic review of clinical evidence for washing and cleansers reported that they are common interventions. Cleansers are indicated in all patients with acne. However, the clinical evidence for their efficacy is not well understood.[49]

Twice-daily face washing may be superior to either once-daily or more frequent washing. Washing too frequently in an attempt to remove surface oils has no added benefit and is not likely helpful, as surface lipids do not affect acne. Contributory lipids are deep in the follicle and are not removed through washing. Antiseptic cleansers, while producing a clean, refreshed feeling, remove only surface dirt, oil, and aerobic bacteria. They do not affect *P. acnes*. Patients should wash no more than twice daily with a mild, nonfragranced opaque or glycerin soap or a soapless cleanser.

Bar soaps are subclassified into true soaps, comprising an alkali and a fatty acid, syndet bars, which use synthetic surfactants, and combars, which include features of both. A study has suggested syndet bars may be superior to true soaps as an acne vulgaris cleansing agent.[50]

Soapless cleansers are an alternative to soaps.[51] Soaps are the most widely used cleansing products, but do not lend themselves to efficient delivery of active drug. Two main disadvantages exist. As soaps are rinsed off, the deposit of active agent is limited, and the high pH required in soaps may degrade some active ingredients and be less tolerable on sensitive skin. Soaps produce a drying effect on the skin due to detergent action. As medicated cleansers require increased contact time, this drying action is pronounced, especially with peeling agents.

Gentle liquid cleansers often contain surfactant systems to remove dirt, sebum, bacteria, and corneocytes from the skin surface. Oil is dispersed from the skin into the surfactant system; however, the active ingredient is sometimes trapped and removed upon rinsing. The balance between cleanliness and drying or irritation should also be considered. Most patients prefer products with foaming action, and these must contain additional secondary surfactants to enhance the foam and condition the skin.

There is no evidence that any particular washing regimen is superior. Evidence-based studies on the use of cleanser or medicated cleansers are lacking or poorly designed with small numbers of patients.[52] It is also difficult to compare studies of different nonprescription formulations even when the same active ingredient is used, as differences in the composition of vehicle may affect cutaneous penetration and vehicles themselves may affect acne. Avoid cream-based cleansers. Scrubbing should be minimized to prevent follicular rupture.

Because the acid pH of skin has an antimicrobial effect, it has been proposed that lowering lesional surface pH (with products such as Herpifix, marketed in Europe) may be correlated to the number of acne lesions. Studies are planned.

Synthetic polyester cleansing sponges abrade the skin surface, removing superficial debris. Considering the structure of comedones, they are unlikely to unseat these lesions. Sponges are available in soft or coarse textures, with or without soap. Circular or rubbing motions will increase irritation. Instruct patients to use single, gentle, continuous strokes on each side of the face, from the midline out toward the ears.

Cationic-bond strips are activated by water. As the strip dries, the cation bonds with the anionic dirt and oil in the pores and removes it when the strip is peeled off.

Shaving

Boys and men with acne should try electric and safety razors to determine which is more comfortable for shaving. When using a safety razor, the beard should be softened with soap and warm water or shaving gel. Shaving should be done as lightly and infrequently as possible, using a sharp blade and being careful to avoid nicking lesions. Strokes should be in the direction of hair growth, shaving each area only once, to minimize irritation.

Comedone Extraction

Comedone extraction has not been widely tested in clinical trials despite long-standing clinical use; however, it is painless and results in immediate cosmetic improvement. Pretreatment with a peeler for 4 to 6 weeks often facilitates the procedure.[47] Following cleansing with hot water, a comedone extractor is placed over the lesion and gentle pressure applied until the contents are expressed. This removes unsightly lesions, preventing progression to inflammation. A correctly sized extractor allows the central keratin plug to extrude through the opening. The small end of a plastic eye dropper, with bulb removed, may also be used. These instruments should be cleaned with alcohol after each use. Some initial reddening may be apparent. If the contents are not expressed with modest pressure, patients should not continue since improper extraction may further irritate the skin. A physician should be consulted if this technique is too difficult for the patient to manage. Since the follicle is difficult to remove completely, comedones may recur between 25 and 50 days following expression. Fewer than 10% of comedone extractions are a complete success, but the process is useful when done properly.[31]

Comedo removal may be helpful in the management of comedones resistant to other therapies. While the procedure cannot affect the clinical course of the disease, it can improve the patient's appearance, which may encourage adherence with the treatment program.

Ultraviolet Light

Although ultraviolet light was recommended in the past for desquamation, the practice is no longer advisable because of the well-established carcinogenic and photoaging effects of ultraviolet exposure. Moreover, inflamed skin is more susceptible to the damaging effects of ultraviolet light. Patients taking tretinoin may show heightened sensitivity.[52]

Before exposure to sunlight, patients with acne should apply sunscreens (sun protection factor [SPF] 15) in alcohol- or oil-free bases and avoid using the acnegenic benzophenones. Sunscreen should be applied as the first product.

Prevention of Cosmetic Acne

Persistent low-grade acne is frequently caused by heavy cosmetic use in women after their mid-twenties. Adolescent acne in younger women may be exacerbated with makeup overuse. The problem is perpetuated when resultant blemishes are concealed with more cosmetics.

Patients should be advised to discontinue oil-containing cosmetics and avoid cosmetic multistep regimens applying various cream-based cleansers and cover-ups. These are commercially advertised and often available with promotional bonuses through Internet shopping. Three-step basic systems usually combine medicated and nonmedicated ingredients. The product names used in marketing these preparations may not make apparent the inclusion of therapeutic agents. Initial steps usually involve cleansers, in lotions or creams, which may contain a multitude of unnecessary ingredients, including medicated peelers, oils, fragrances, and preservatives. Active ingredients including salicylic acid, sulfur, or benzoyl peroxide are often included in subtherapeutic or low doses. The second step is generally a water- or alcohol-based "toner" or "refresher," which might contain medicated mild comedolytic agents such as α-hydroxy acids (eg, glycolic acid), or even a humectant such as glycerin. The final product, often called intensive or repairing solutions, usually contains the lowest strength of peelers such as benzoyl peroxide, sulfur, or salicylic acid; plus potentially sensitizing fragrances and preservatives; or oil-soluble sunscreens not identified on the label. Bases may have significant oil content. There may be additional products such as masks or spot treatments that supplement the base routine of three steps. Multiple-step cosmetic programs are often costly and should be avoided in favor of simple cleansers and more effective single-ingredient peelers at optimal concentrations.

The term *noncomedogenic* may refer to either water-based vehicles or products that are free of substances known to induce comedones. They are not necessarily oil-free. Water-based cosmetics may contain significant amounts of oil in the form of undiluted vegetable oils, lanolin, fatty acid esters (butyl stearate, isopropyl myristate), fatty acids (stearic acid), fatty acid alcohols, cocoa butter, coconut oil, red veterinary petrolatum, and sunscreens containing benzophenones. Water-based products are more likely to contribute to pore blockage than oil-free products.

Oil-free makeups are well-tolerated and lipstick, eye shadow, eyeliner, eyebrow pencils, and loose face powders are relatively innocuous. Heavier, oil-based preparations, particularly moisturizers and hairsprays, clog pores and accelerate comedone formation.[53]

Patients should restrict cosmetic use including makeup, moisturizers, or sunscreens to products labeled oil-free rather than water-based. Cover-up cosmetics for acne are available in several skin tones and in lotion and cream forms. They often contain peeling agents, antibacterial agents, or hydroquinone. Most contain sulfur. They may be applied as cosmetics two or three times daily, over the entire face or to individual lesions. Because the spread time of oil-free makeup is decreased, best results are achieved if applied to one-quarter of the face at a time. Topical medication should be applied after gentle cleansing and a foundation lotion may be used sparingly as a concealer.[54-56]

Because the action of most therapeutic acne agents is to dry the skin, the use of nonspecific moisturizers is counterproductive. Active agents, such as α-hydroxy acids (glycolic, lactic, pyruvic, and citric acids), may be present in a cosmetic formulation, since they reduce corneocyte adhesion.[57] Patients with acne should be restricted to oil-free α-hydroxy acid products unless necessary because of treatment with strong drying agents or isotretinoin.

Cosmetics, if correctly prescribed, may improve the performance of the therapy, whereas incorrect procedures and/or inadequate cosmetics may worsen acne. Clinicians should make informed decisions about the role of various cosmetics and to identify the appropriate indications and precautions. The choice of the most effective product should take into consideration the ongoing pharmacologic therapy and acne type/severity as well.[58]

Vehicles

Topical medication is a staple in treating mild-to-moderate acne because it is an efficient way to deliver medication to the site of action and involves decreased risk of exposure to ingredients. Since local irritation from the vehicle can lead to poor adherence and outcomes, it is essential to choose a vehicle which is effective and well tolerated. Topical agents are absorbed primarily through passive diffusion via appendageal transcellular or intracellular pathways. As the active drug travels, it may undergo chemical changes in the skin or by the vehicle.[59]

The formulation of an acne vehicle must consider the technical characteristics of maintaining and delivering the drug in an active state together with the need for an elegant product that is well tolerated and the patient will enjoy using, so that it is more likely to be applied as required and deliver the full benefit. Physically and chemically, the vehicle will be used with one or more of the following goals: reduce excess oil, control bacteria associated with acne, reduce the effects of hyperkeratinization, and unclog pores. Performance, safety, and stability should be maximized while addressing technical and commercial factors.

Immiscible liquids might be delivered in oil-in-water or water-in-oil emulsions. In addition to having undesirable oil content, these vehicles also contain humectants, thickeners, preservatives, and fragrance, all of which may be problematic.

Solutions are simpler formulations. They are often used as the soaking liquid for fibrous cloth wipe products. The shelf life depends upon whether multiple wipe packages are resealable, and whether the solvent volatility will affect storage and active agent availability or cause crystallization. Solutions are used mainly with topical antibiotics, which are often dissolved in specific types of alcohol. Although some antibiotics are only soluble in ethyl alcohol, isopropyl alcohol is generally better able to remove oil from the skin surface and is preferred for nonmedicated vehicles. Solutions and washes can be more easily applied to large areas such as the back.[60] Nongreasy solutions, gels, lotions, and creams should be selected as bases for topical acne preparations. Lotions and creams will contain some oil-phase ingredients. Discourage moisturizers and oil-based products. Lotions are slightly less drying than gels, and creams are more emollient. Gels are very useful as they are mixtures of water or alcohol and totally oil free. Many gels contain ethanol or isopropyl alcohol. Propylene glycol is sometimes present in small amounts to add viscosity and lessen the drying effects of strong peeling agents. Gels are drying but may cause a burning irritation in some patients and may prevent certain kinds of cosmetics from adhering to the skin.[53] Propylene glycol gels are easy to apply and dry without a visible or sticky film. Nonalcoholic gels may be so effective and less drying than alcoholic solutions. Alcoholic or acetone gels are usually more drying and provide better penetration of the active ingredient.

Consider the patient’s skin type and preferences in the choice of vehicle for topical agents. Patients with oily skin often prefer vehicles with higher proportions of alcohol (solutions and gels), while those with dry or sensitive skin prefer nonirritating lotions and creams. Hydrating and emollient products are often recommended to patients using drying treatment therapies, such as isotretinoin, to control adverse effects and improve adherence to treatment. Lotions can be used with any skin type and can be easily spread over hair-bearing skin, but they will cause burning or dryness if they contain propylene glycol. Compatibility of vehicles and agents with cosmetics should also be considered.

The focus of innovation has been optimal formulations of problematic drugs. A fixed topical alcohol-free aqueous gel combination of clindamycin phosphate 1.2% and tretinoin 0.025% given once daily simplifies administration and encourages adherence. Creamy wash and gel hydrophase options for benzoyl peroxide reduce the irritation of this drug.[61]

The importance of vehicle effects in topical therapy has been demonstrated in placebo effect literature.[61] The percent contribution of vehicle (placebo) toward efficacy of reduction of lesions counts of eight commonly prescribed topical preparations at the end of 10 to 12 weeks of daily administration has been reported as a mean value of 55% (range 35%-82%).

How to Use Topical Preparations

Topical preparations should not be applied to individual lesions but to the whole area affected by acne to prevent new lesions from developing. Care should be advised in applying around the eyelid, mouth, and neck (to avoid chafing). Lotions should be applied with a cotton swab once or twice a day after washing or at bedtime if they leave a visible residue. Skincare products may cause skin dryness and redness particularly at the early stages of the treatment. Should this occur, the product should be applied more infrequently, the treatment should be stopped for a while or another topical product tried. To reduce irritation a topical vehicle with high water content may be applied over the medicinal product after a few minutes; the irritation usually subsides as the skin becomes accustomed to the topical skincare product.

Psychologic Approaches, Hypnosis, and Biofeedback

The psychologic effects of acne may be profound. The American Academy of Dermatology expert workgroup unanimously concluded that effective acne treatment can improve the emotional outlook of patients.[62] There is weak evidence of the possible benefit of biofeedback-assisted relaxation and cognitive imagery.[63,64]

Dressings

A pilot double-blind, randomized study of 20 patients has shown some benefit of treatment with a hydrocolloid acne dressing when compared with tape dressings for improving mild-to-moderate inflammatory acne vulgaris. Results showed greater reduction over 3 to 7 days in the overall severity of acne and inflammation, along with greater improvement in redness, oiliness, dark pigmentation, and sebum casual level. Less ultraviolet B light reaches the skin surface with the hydrocolloid dressing in place.[65,66]

Pharmacologic Therapy

Successful pharmacologic therapy must address one of the four mechanisms involved in the pathogenesis of acne. Numerous agents are available that prove one or more of these actions and are therefore effective. However, the choice of active pharmacologic therapy depends on severity.

Mechanisms of drug action relating to acne pathogenesis are illustrated in Fig. 117-2.

Drug Treatments of First Choice

There is concordance among key opinion leaders in different settings regarding recommendations for drugs of choice for management of acne—the Global Alliance 2018 and the 2016 European Guidelines.[24,32,67]

Managing Acne

For comedonal, noninflammatory acne Active agents of first choice include those that correct the defect in keratinization by producing exfoliation most efficaciously. Topical retinoids, in particular, adapalene, or a fixed combination with a retinoid (eg, adapalene plus benzoyl peroxide) can be recommended as drugs of choice.[24,32] Benzoyl peroxide or azelaic acid or salicylic acid can be considered, as alternatives (lower strength recommendation).[24,32] Limitations can apply that may necessitate the use of a treatment with a lower strength of recommendation as a first-line therapy (eg, financial resources and reimbursement limitations, legal restrictions, availability, drug licensing). Because the comedone is the initial lesion even in inflammatory acne, these agents are used to correct the defect in keratinization in all cases of acne.

For mild-to-moderate papulopustular inflammatory acne It is important to reduce the population of *P. acnes* in the follicle and the generation of its extracellular products and inflammatory effects. Either the fixed-dose combination (adapalene and benzoyl peroxide) or benzoyl peroxide or topical retinoid or azelaic acid is strongly recommended as first choice therapy (high strength recommendation).[24,32,67] In case of more widespread disease, for the treatment of **moderate papulopustular inflammatory acne**, the fixed-dose combination is preferred, with or without hormonal therapy and/or antibiotic, particularly if the trunk is involved.[67]

Low-strength recommendations are offered as considerations for treatment if there are limitations that apply in selecting a first-choice agent. The choices would be blue light monotherapy, alternate combination therapy (such as fixed-dose combination of erythromycin and tretinoin, fixed-dose combination of isotretinoin and erythromycin) or oral zinc. In case of more widespread disease, a combination of a systemic antibiotic with either benzoyl peroxide or with adapalene in fixed combination with benzoyl peroxide can be considered.[24,32]

For moderately severe or severe papulopustular or moderate nodular acne The fixed-dose combination with an oral antibiotic is preferred. Alternatively, oral isotretinoin or oral hormonal therapy can also be added.[68] if there are limitations to usethese agents, considerations could be given to oral antiandrogens in combination with oral antibiotics or topical treatments, or systemic antibiotics in combination with benzoyl peroxide (low strength recommendation).

Managing Very Severe Acne

For nodular or conglobate acne In males, monotherapy with oral isotretinoin is strongly recommended as the drug of first choice (high strength recommendation).[24,32] As alternative agents, a retinoid fixed combination or oral antibiotics can be recommended. For females, oral isotretinoin plus antiandrogenic hormonal therapy is preferred. Alternatively a fixed combination retinoid with oral antibiotics (consider high dose) and/or oral antiandrogenic hormonal therapy can be recommended.[68]

For maintenance therapy for acne The most frequently recommended agents are topical retinoids or retinoid and benzoyl peroxide fixed dose combinations.[67] The most extensively studied maintenance treatment (four controlled trials) has been adapalene regimens.[24,32] Other published options include tazarotene or tretinoin. In general, maintenance therapy is begun after a 12-week induction and continues for 3 to 4 months. Continuing improvement using this schema is achieved, with relapse occurring when patients stop treatment, suggesting a longer duration of maintenance therapy is likely to be beneficial. Topical azelaic acid is an alternative to topical retinoids for acne maintenance therapy, with advantageous efficacy and safety profiles for long-term therapy. To minimize antibiotic resistance, long-term therapy with antibiotics is not recommended as an alternative to topical retinoids. If an antimicrobial effect is desired, the addition of benzoyl peroxide to topical retinoid therapy is preferred.

Published Guidelines

In general, recommendations should be based on critical appraisal and interpretation of the literature combined with clinical experience. There is considerable heterogeneity in the acne literature. The large number of products and product combinations, and the scarcity of comparative studies, has led to disparate opinions and few recommendations are evidence-based. Various evidence-based guidelines, available from multiple American, Canadian, European, Scandinavian, and South African sources from 2005 to 2018, do not provide concordance or clarity on all issues.

The 2016 European Guidelines for the Treatment of Acne focus primarily on major treatments, but do not review general management issues such as psychologic determinants, scarring, and diet.[24,69] Where relevant, specific information from multiple sources will be integrated into the therapy section that follows.

An expert committee of the American Academy of Dermatology redefined guidelines for acne therapy in 2016 (Table 117-1).[68] These guidelines address the management of adolescent and adult patients presenting with acne but not the consequences of disease, including the scarring, postinflammatory erythema, or postinflammatory hyperpigmentation. In 2009, the Global Alliance to Improve Outcomes in Acne updated their 2003 recommendations to review new information about pathophysiology and treatment and included current published data on relevant issues.[70] In 2018, the Global Alliance published a further update providing relevant clinical guidance to healthcare practitioners managing patients with acne, with an emphasis on areas where the evidence base may be sparse or needs interpretation for daily practice. They provided 10 consensus recommendations, based on the 2016 American Academy and European Guidelines.[67]

TABLE 117-1

Evidence Chart for Recommendations for Managing Acne Vulgaris

Recommendation	Strength of Recommendation	Level of Evidence
Grading/classification system	B	II, III
Microbiologic testing	B	II, III
Endocrinologic testing	B	I, II
Topical therapies		
Benzoyl peroxide	A	I, II
Topical antibiotics (eg, clindamycin, minocycline, and erythromycin)	A	I, II
Combination of topical antibiotics and benzoyl peroxide	A	I
Topical retinoids (eg, tretinoin, adapalene, tazarotene, and trifarotene)	A	I, II
Combination of topical retinoids and benzoyl peroxide/topical antibiotic	A	I, II
Azelaic acid	A	I
Dapsone	A	I, II
Salicylic acid	B	II
Systemic antibiotics		
Tetracyclines (eg, doxycycline, minocycline, and sarecycline)	A	I, II
Macrolides (eg, azithromycin and erythromycin)	A	I
Trimethoprim (with or without sulfamethoxazole)	B	II
Limiting treatment duration and concomitant/maintenance topical therapy	A	I, II
Hormonal agents		
Combined oral contraceptives	A	I
Spironolactone	B	II, III

Oral corticosteroids	B	II
Isotretinoin		
Conventional dosing	A	I, II
Low-dose treatment for moderate acne	A	I, II
Monitoring	B	II
iPLEDGE and contraception	A	II
Miscellaneous therapies and physical modalities		
Chemical peels	B	II, III
Intralesional steroids	C	III
Complementary and alternative therapies (eg, tea tree oil, herbal, and biofeedback)	B	II
Role of diet in acne effect of glycemic index	B	II
Dairy consumption	B	II

Data from Reference 68.

The Alliance recommendations statements were as follows[67]:

1. Retinoids have an essential role in treatment of acne. For most patients with inflammatory acne, comedonal acne, or both, a topical retinoid plus benzoyl peroxide is first-line therapy.[24,68,69]
2. The role of antibiotics in acne therapy has changed. Neither topical nor systemic antibiotics should be used as monotherapy for acne treatment.[69,71]
3. Oral isotretinoin should be first-line therapy for very severe (cystic and conglobate) acne.[69]
4. Oral isotretinoin therapy should proceed until full clearance of acne. Additional studies are needed to define a total cumulative dose that maintains remission.
5. Acne flare with oral isotretinoin can be minimized by initiating therapy at a low dose.
6. Most patients with acne should receive maintenance therapy with a topical retinoid.
7. Azelaic acid cream 20% or gel 15% is a useful acne treatment in pregnant women and patients with acne and PIH.
8. At present, devices that use laser, intense pulsed light, or photodynamic therapy should not be considered first-line treatment for inflammatory acne.
9. A minority of women 25 years of age have acne lesions localized only to the lower face. Topical retinoids with or without benzoyl peroxide are important components in therapy of adult acne.
10. Early and effective treatment is important to minimize potential risk for acne scarring.

General Information Regarding Efficacy and Safety

The guidelines and recommendations of the American Academy of Dermatology considered the efficacy and safety of various treatments, such as topical agents, systemic antibacterial agents, hormonal agents, isotretinoin, miscellaneous therapies, complementary and alternative therapies, and dietary restriction, based on levels of evidence and best clinical practice.[68] More specific information about the efficacy and safety of each of these specific modalities is outlined below in sections on each individual agent.

Alternative Drug Treatments

Complementary and Alternative Medications People with acne often turn to complementary and alternative medicine (CAM), such as herbal medicine, acupuncture, and dietary modifications, because of their concerns about the adverse effects of conventional medicines. Although these products might be well tolerated, very limited data exist regarding their safety and efficacy.

There is increasing interest in the use of CAM as adjuvant or single therapies: in America, 7% people report using a complementary medicine, and 2% report seeing a complementary medicine practitioner.[72] Traditional Chinese medicine has been widely used to treat acne for many years, based on a diagnosis from a traditional Chinese medicine perspective according to the different syndromes of acne.
